Many, if not all, viruses employ evasion strategies to circumvent aspects of the immune system, allowing them time to replicate further or escape detection³⁵ (Table 27.3). One such mechanism may involve killing or infecting APC. Viruses may also delay or prevent apoptosis induced by CTL within infected cells. Other viral evasion measures aimed at the CD8 T-cell-mediated antiviral defense system serve to inhibit antigen processing, thereby minimizing effector CTL induction. Many viruses also downregulate MHC molecules on the surface of infected cells to escape CTL killing. In addition, viruses may produce various mimics or modulators/inhibitors of cytokines, chemokines, or other components of the immune system or their receptors. Viruses also resort to antigenic hypervariability to escape antibody or T-cell recognition. This can occur during transmission from host to host (i.e., influenza virus), or within hosts during chronic infection through the generation of viral escape mutants (i.e., HIV).

The success of many viral pathogens rests in their ability to subvert the host immune response. The most successful human viruses can escape the immune system and persist for the life of the host.³⁶ Two well-studied examples of this are CMV and EBV. T-cell responses to these viruses are prominent and readily detectable in people, yet the immune system is unable to clear either pathogen completely. However, these viruses generally remain undetectable in immunocompetent individuals. Other viral infections, such as those caused by the herpes viruses HSV and VZV, are marked by periods of latency, where no virus can be detected. Yet periods of viral reactivation, often triggered by stress, can lead to episodes of disease. These are controlled by the immune response which plays a central role in controlling herpes virus latency.³⁷

Many of the most medically important human viruses are associated with persistent viremia. These include chronic infections such as HIV, HCV, HBV, and human T-lymphotropic virus (HTLV), among others.³⁸ Such viral infections are marked by high levels of persisting antigen and can result in skewed T-cell immunodominance hierarchies, altered tissue localization of immune cells, and severely impaired T-cell function. This altered T-cell function is hierarchical and appears to correlate directly with antigen levels, resulting in functional T-cell defects ranging from reduced cytokine production and altered proliferative capacity (exhaustion) to death (deletion) of the responding T cells³⁸ (Fig. 27.3). This is in stark contrast to normal memory T-cell development which occurs in the

Table 27.3 Mechanisms and examples of viral immune evasion

Mechanism	Example
Interference with viral antigen processing and presentation	HSV (ICP47), EBV (EBNA-1), HIV (Nef, Tat), HPV (E5), CMV (UL6)
Evasion of NK cell function	HIV (Nef), EBV (EBNA-1), CMV (UL40, UL18)
Inhibition of cell apoptosis	Adenovirus (RID complex and E1B), HIV (Nef), EBV (BHRF-1)
Destruction of T cells	HIV
Interference with antiviral cytokines and chemokines	EBV (IL-10 homologue), CMV (US28 chemokine receptor homologue), vaccinia virus (IL-18-binding protein), HIV (Tat chemokine activity)
Inhibition of complement action	HSV, pox viruses
Inhibition of DC maturation	HSV, vaccinia virus
Frequent antigenic variation	Influenza virus, HIV
Infection of immune privileged site	Measles virus, VZV and HSV (neurons)
Immune exhaustion	HIV, HCV, HBV

CMV, cytomegalovirus; DC, dendritic cell; EBV, Epstein–Barr virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HPV, human papillomavirus; HSV, herpes simplex virus; IL-18, interleukin-18; NK, natural killer; RID, receptor internalization and degradation; VZV, varicella-zoster virus.

Fig. 27.3 Hierarchical model of T-cell exhaustion during persistent viral infection. T-cell function (cytokine production, killing, and proliferative potential) is negatively influenced by increasing levels of antigen. Low levels of persistent antigen may lead to partial loss of function and intermediate levels of programmed death (PD)-1 expression. High, sustained levels of antigen over time can lead to full loss of function, high levels of PD-1, and eventually cell death (deletion).

absence of persisting antigen (see previous section). Recent studies have demonstrated that signaling through programmed death (PD)-1 on effector CTL causes exhaustion during chronic infections.³⁹ This pathway may be essential for preventing excessive immunopathology by effector T cells, yet appears to contribute directly to failed immunity to HIV infection,⁴⁰ and other chronic human viral infections.³⁹ These studies implicate this pathway as a potential therapeutic target.

IMMUNOPATHOLOGY AND AUTOIMMUNITY

Immune responses against virus-infected cells often result in tissue damage, especially if cell killing is involved. If this effect is brief and without long-term consequences, it is usually judged as an immunoprotective

event. A prolonged tissue-damaging effect resulting from an immune reaction against viruses is considered immunopathology.⁴¹ Such situations most commonly involve persistent viruses, themselves at best modestly cytotoxic in the absence of an immune reaction. Chronic tissue damage initiated by viruses may also result in the response becoming autoreactive. Accordingly, some autoimmune diseases may be initiated or exacerbated by virus infections, although this notion has yet to be proved in the case of any human autoimmune disease.⁴² Circumstantial evidence exists for a virus link in multiple sclerosis (MS), insulin-dependent diabetes, and possibly systemic lupus erythematosus (SLE). In MS, many viruses have been isolated from patients, though no specific one tied to the disease. The current hypothesis is that viral infections set up an inflammatory environment that may exacerbate or tip the balance towards disease in genetically susceptible individuals.⁴²

Immunopathological reactions involving viruses have several mechanisms, but T cells are usually involved as orchestrators of the inflammatory events (Table 27.4). The clearest example of immunopathology involving a virus is lymphocytic choriomeningitis virus (LCMV) in the mouse. This model has dominated ideas and has set several paradigms in viral immunology in general. The first virus-induced immunopathology lesion recognized was glomerulonephritis and arteritis, noted in mice persistently infected with LCMV. The lesions were assumed to represent inflammatory reactions to tissue-entrapped immune complexes that activate complement. Similar immune complex-mediated lesions occur in other infections, but rarely have viral antigens been shown to contribute to the antigen component of the complex. An example where the inclusion of viral antigen in immune complexes has been demonstrated is chronic hepatitis B virus infection of humans. Autoimmune diseases such as SLE and rheumatoid arthritis also result from immune complex-mediated tissue damage. However, evidence linking viruses to the etiology or pathogenesis of SLE is scarce, since the immune complexes in SLE do not appear at any stage to include viral antigens.

Thanks largely to the LCMV model, it is clear that CD8 T-cell recognition of viral antigens can result in tissue damage. In LCMV, damage

Involvement of CD4 T cells that produce Th2 cytokines

Respiratory syncytial virus-induced pulmonary lesions

Involvement of antibody

Glomerulonephritis in chronic hepatitis B
 Dengue hemorrhagic fever

occurs in the leptomeninges of immunocompetent mice infected intracerebrally. Hepatitis can also occur in mice infected intravenously. Neither lesion becomes evident if the CD8 T-cell response is suppressed. CD8 T-cell-mediated immunopathology is also a likely explanation for acute hepatitis caused by some other hepatitis virus strains. The mechanisms involved in hepatitis B infection have been carefully analyzed in a mouse model in which the whole HBV was expressed as a transgene.⁴³ In this model, CD8 cells organized the immunopathology reaction, but the process appeared complex. Initially, CTL-mediated cell killing events occurred, but since hepatocytes die by apoptosis it was not clear how this related to subsequent inflammatory events. However, the CD8 T cells also released numerous cytokines and chemokines that recruited inflammatory cells, primary macrophages. Interestingly, liver-infiltrating CTL have been shown to be inhibited by PD-1–PD-L1 interactions, which may greatly reduce the severity of local immunopathology.⁴⁴

Additional viral immunopathology models where lesions result primarily from CD8 T-cell involvement include myocarditis and insulin-dependent diabetes associated with coxsackie B virus infection.⁴² In both instances, CD8 T cells mainly orchestrate events, but tissue damage may result from the bystander effects of cytokines. This is especially likely in the diabetes model, as the coxsackievirus cannot be demonstrated in islet cells. The diabetes model is of interest, however, because the events observed closely resemble those that occur in an autoimmune model of diabetes. However, attempts to relate viral infection directly to the etiology of human diabetes have so far failed.⁴²

Immunopathological reactions against virus can also involve CD4 T cells.⁴¹ One well-studied example involves persistent infection with Theiler's virus in mice⁴⁵ (Fig. 27.4). This infection causes a demyelinating syndrome that resembles the experimental autoimmune disease experimental allergic encephalomyelitis (EAE). In both situations, CD4 T cells that produce Th1 cytokines appear to be pathologic. Furthermore, in both models an increase in the involvement of myelin-derived autoantigens

CLINICAL RELEVANCE**HYPOTHESIZED ROLE OF VIRUSES IN AUTOIMMUNITY**

- >> Molecular mimicry: similar epitopes shared by virus and host
- >> Bystander activation: chronic release of cytokines and host antigens activates local autoreactive lymphocytes
- >> Viral persistence: chronic viral antigen presentation on host cells leads to prolonged immunopathology

occurs as the disease progresses. Once again, such observations indicate the possible role of a virus in an autoimmune disease. With the Theiler's virus model the virus persists in the nervous system and chronically stimulates CD4 T cells to secrete an array of cytokines. The demyelinating events appear to result from cytokine action on oligodendrocytes. Myelin components such as myelin basic protein, proteolipid protein, and myelin oligodendroglial glycoprotein may be released and participate as additional antigens in immunoinflammatory events. This scenario is referred to as epitope spreading.

Another model of virus-induced immunopathology involving CD4 T cells of the Th1 phenotype is stromal keratitis caused by herpes simplex virus infection (Fig. 27.5).⁴⁶ The pathogenesis of this immunopathology lesion is unusual in that it occurs and progresses when viral antigens can no longer be demonstrated. The chronic immunoinflammatory lesions are mainly orchestrated by CD4 T cells, but multiple early events occur that induce the subsequent pathology. Viral replication, the production of certain cytokines (IL-1, IL-6, IL-12, and CXCL8) and chemokines, recruitment of inflammatory cells (such as neutrophils), and neovascularization of the avascular cornea all precede immunopathology.⁴⁶ Recent work has also highlighted the role of Th17 CD4 T cells in autoimmune inflammation and immunopathology, and the role of TGF- β and IL-23 in driving these cells.²³ Whether this IL-17/IL-23 axis is important for viral pathogenesis remains to be determined.

A further mechanism of viral-induced immunopathology and autoimmunity is molecular mimicry.⁴⁷ Molecular mimicry represents shared antigenic epitopes, either B-cell or T-cell antigens, between the host and virus (Chapter 50). The idea began for streptococci and their association with rheumatic fever. With human autoimmune disease, there is little direct support for viral molecular mimicry; however, some animal models have been used to prove the theoretical case, using a model where a viral antigen is expressed as a self-protein in the islet cells of the pancreas. In this model, subsequent infection with the virus induces diabetes. However, this is not true mimicry and may be more closely related to viral antigen persistence in a model such as Theiler's disease.

Recently it has become apparent that immunopathology can result from an imbalance in the types of functional effector T cells induced. Tissue damage can be the bystander consequence of a dysregulated immune response to infection. The magnitude of the response can be influenced by the activity of one or more types of regulatory T cells (Tregs) (Chapter 16). Recent research has emphasized the role of

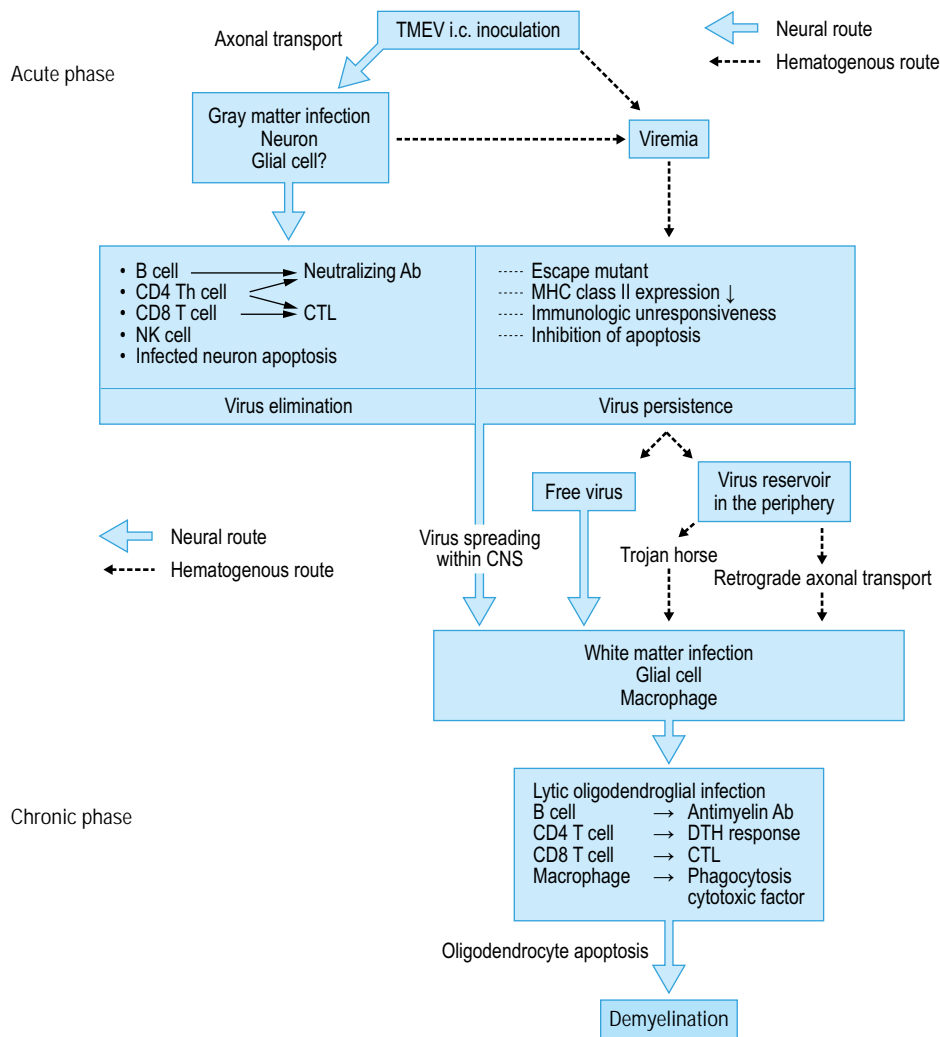

Fig. 27.4 Possible scheme of events set off by virus infection, such as Theiler's virus that results in demyelination. natural CD4⁺CD25⁺FoxP3⁺ Tregs, which are considered important for controlling the onset of autoimmune disease. These Tregs can also influence the magnitude of the protective immune response to viruses.⁴⁸ Natural FoxP3⁺ Tregs, or other types of regulatory T cells that produce an abundance of the anti-inflammatory cytokines IL-10 and TGF- β , are known to be involved in limiting excessive immunopathology associated with ongoing immune responses to persistent viral infection. Evidence for this has been reported in several viral infections such as HCV and HIV.⁴⁸ It is interesting to note that Treg function may be both beneficial to the host, by limiting immunopathology, and detrimental, due to reduced local T-cell responses and thus prolonged viral persistence.

CONCLUSIONS

Humans are infected by several pathogenic viruses, the number of which would be far greater but for the presence of innate and adaptive mechanisms of immunity. As it is, relatively few cause major clinical problems or lethality, except when the immune response is impaired, absent, or dysfunctional. However, during immune defects pathogenic viruses become more consequential and viruses that are unremarkable agents in immunocompetent persons become highly significant. An excellent example is cytomegalovirus infection. A high proportion of the population is infected, yet only those individuals who are immunosuppressed in connection

Fig. 27.5 Example of herpetic stromal keratitis (HSK) in the human eye after herpes simplex virus-1 (HSV-1) infection. Inflammation of the eye and eyelid can be observed, as well as neovascularization, and substantial necrosis, ulceration, and opacity of the cornea.

KEY CONCEPTS

PHASES OF IMMUNITY AFFECTED BY REGULATORY T CELLS

with cancer treatment, transplantation, or acquired immunodeficiency syndrome (AIDS) caused by HIV display complications. This is true for many common bacterial and viral agents, such as HSV, whose infections become far more frequent and severe in AIDS patients.

As our understanding of the mechanisms underlying innate immune defenses, antigen presentation, T- and B-cell responses and Tregs continues to improve, so too does the ability to design better vaccines and therapies to boost the immune control of viral infections. Although this remains a challenging goal, particularly for many human viruses such as HIV, HCV, and HSV, these rapid advances continue to provide many avenues for further investigation.

Immune responses to protozoans

Peter C. Melby, Gregory M. Anstead

28

Protozoal infections are an important cause of morbidity and mortality worldwide (Table 28.1). Protozoan pathogens exact their major toll in the tropics, but infection with these parasites remains a significant problem in developed countries, owing to travel to and emigration from developing countries, the susceptibility of AIDS patients to opportunistic protozoans, and episodic transmission within communities.

Protozoan pathogens make up a group of highly diverse organisms that use a wide array of mechanisms of pathogenesis to evade the host immune response (Table 28.2). There are numerous targets for the intracellular protozoan parasites, including erythrocytes (*Babesia* and *Plasmodium*), macrophages (*Leishmania* and *Toxoplasma gondii*), or multiple cell types (*Trypanosoma cruzi*). The luminal parasitic protozoan may be extracellular, such as the amebae and the flagellates (*Giardia* and *Trichomonas*), or primarily intracellular, such as the coccidian parasite *Cryptosporidium*.

The innate and acquired immune responses to the protozoan pathogens are summarized in Table 28.3. Neutrophils and macrophages are the effector cells that mediate the innate response against the extracellular protozoan parasites. The natural killer (NK)-cell-activated macrophage system is central to the innate response to the intracellular parasites (Fig. 28.1) (Chapters 3 and 18). The innate cytokine response also plays a critical role in the generation of the adaptive immune response. For the intracellular pathogens (e.g., *Leishmania* spp., *T. cruzi*, *T. gondii*), the early production of IL-12 and IFN- γ drives the differentiation of T cells to a protective Th1 phenotype. In most cases CD4 T cells play a primary role in acquired cellular immunity, but CD8 T cells may play a critical role through cytokine production (e.g., *Plasmodium* spp., *T. cruzi*, *T. gondii*) or direct cytotoxic activity (e.g., *Cryptosporidium*). For the parasites that have an extracellular stage (e.g., *Plasmodium* spp., the trypanosomes, *Giardia* and *Trichomonas*), specific antibodies play a role in the acquired immune response.

Intensive effort has been dedicated to the development of effective vaccines for protozoal diseases, but despite their significance none has so far reached the stage of clinical use. A review of all the potential vaccine candidates is beyond the scope of this chapter and the reader is referred to a number of excellent reviews.¹⁻⁴ A discussion of the immune responses to some of the individual protozoal pathogens follows.

KEY CONCEPTS

HOST DEFENSE AGAINST PROTOZOA

- >> Interaction of the parasite with host cells induces an array of cytokines which stimulate the innate and adaptive immune responses to eliminate the pathogen, and/or cytokines that inhibit or downregulate the antiparasitic responses to enable the initiation of tissue parasitism.
- >> The outcome of infection is determined by the balance between the infection-promoting and the host-protective cytokines and effector cells. Often there is a mixed response, resulting in a persistent subclinical infection.
- >> A persistently infected host may develop clinical disease if there is a waning of the immune mechanisms (e.g., in AIDS) that are critical to the control of infection.

■ PLASMODIUM SPP. ■

PATHOGENESIS

Soon after sporozoites of the *Plasmodium* spp. are injected into the bloodstream by the *Anopheles* mosquito they invade hepatocytes and undergo schizogony (asexual reproduction). A dormant form of *P. vivax* and *P. ovale* (hypnozoites) can reside within hepatocytes for months before causing a clinical bloodstream infection. Following schizogony, merozoites are released from ruptured hepatocytes into the bloodstream, where they invade red blood cells to produce ring-stage parasites. These parasites mature into trophozoites, which again undergo schizogony, leading to rupture of the erythrocyte and the release of merozoites. The merozoites then invade fresh red blood cells (RBC), or develop into male or female gametocytes that can then be picked up by another feeding mosquito to continue the transmission cycle.

Table 28.1 Worldwide significance of the major protozoal infections (Summarized from Markell E, John D, Krotoski W. Medical parasitology. Philadelphia: WB Saunders, 1999⁴⁴)

Parasite	Estimated worldwide cases (annual mortality)	Clinical manifestations
<i>Trypanosoma brucei</i> complex	100 000 new cases/year (5000 deaths)	Intermittent fever, lymphadenopathy, meningoencephalitis
<i>Trypanosoma cruzi</i>	24 million (60 000 deaths)	Asymptomatic infection; dysrhythmias or chronic heart failure; hypertrophy and dilation of the esophagus, colon
<i>Entamoeba histolytica</i>	50 million (100 000 deaths)	Asymptomatic infection, diarrhea, dysentery, or liver abscess
<i>Cryptosporidium parvum</i>	Prevalence 3–10% in patients with diarrhea in developing countries	Self-limited diarrhea in immunocompetent persons, severe intestinal and biliary disease in AIDS patients
<i>Cyclospora</i> spp.	Prevalence of ~10% in developing countries	Relapsing watery diarrhea
<i>Giardia lamblia</i>	200 million (most common in young children and immunocompromised)	Asymptomatic infection, chronic diarrhea
<i>Isospora belli</i>	Incidence unknown, rare in immunocompetent persons	Self-limited diarrhea in immunocompetent persons, chronic diarrhea in AIDS patients
<i>Leishmania</i> spp.	10–50 million people infected, 1.2 million new cases per year	Asymptomatic infection; skin ulcers or nodules; destructive oropharyngeal lesions; visceral disease with fever, hepatosplenomegaly, cachexia, pancytopenia
<i>Plasmodium</i> spp.	400–490 million (<i>P. falciparum</i> : >2 million deaths/year, primarily children)	Fever with potential complications of severe hemolysis, renal failure, pulmonary edema, cerebral involvement
<i>Toxoplasma gondii</i>	Several hundred million people infected worldwide. 5–70% of healthy US adults are seropositive	Self-limited fever, hepatosplenomegaly; lymphadenopathy and encephalitis (reactivation in AIDS patients); congenital infection, with fetal death, chorioretinitis, meningoencephalitis
<i>Trichomonas vaginalis</i>	170 million/year	Asymptomatic infection, vaginal discharge, urethritis

The clinicopathological features of malaria are caused by the intra erythrocytic stage. Schizogony and rupture of RBCs is associated with fever. Much of the tissue damage is mediated by the adherence of *P. falciparum*-infected RBCs to endothelial cells through multiple ligand–receptor interactions and plugging of microcapillary beds. Several *P. falciparum* trophozoite proteins, most notably belonging to the erythrocyte membrane protein-1 (EMP-1) family, interact either directly or indirectly with the RBC membrane, resulting in abnormalities that promote cytoadherence.^{5,6} A number of endothelial adhesion molecules, including intercellular adhesion molecule-1, vascular cell adhesion molecule-1, thrombospondin, E-selectin, CD31, CD36, hyaluronic acid, and chondroitin sulphate A, mediate cytoadherence. Sequestration of parasitized RBCs in the capillary beds offers a survival advantage to the parasites by removing them from circulation through the spleen. Along with the sequestered RBCs there is accumulation of intravascular macrophages, neutrophils and platelets.

The induction of a proinflammatory cytokine cascade and counter-regulatory responses plays a central role in the pathogenesis of *P. falciparum* malaria and its complications. Parasite antigens, particularly those having glycosylphosphatidyl inositol membrane anchors, released during the rupture and reinvasion of RBCs, activate the innate immune response through interaction with receptors on host cells. The production of proinflammatory cytokines (IL-1, TNF- α , IL-12, and IFN- γ), which leads to fever, expression of endothelial adhesion molecules, and cytoadherence, is mediated in part by TLR-2 and is MyD88 dependent.^{5,6} The induction of nitric oxide (NO) synthesis by endothelial cells may also contribute to inflammatory lesions in the brain. Cerebral malaria in the mouse model can be prevented by neutralization of TNF- α , and the risk of cerebral malaria in children is increased when the child has an allele containing a TNF- α promoter polymorphism that is associated with increased TNF- α transcription.

Table 28.2 Principal mechanisms of immune evasion by protozoal pathogens

Mechanism of immune evasion	Pathogen
Antigenic variation	<i>Plasmodium</i> spp., <i>Trypanosoma brucei</i> , <i>Giardia lamblia</i> , <i>Trichomonas vaginalis</i>
Entry into red blood cells	<i>Plasmodium</i> spp., <i>Babesia microti</i>
Resistance to complement-mediated lysis	<i>Leishmania</i> spp., <i>Trypanosoma cruzi</i> , <i>Trypanosoma brucei</i> , <i>Entamoeba histolytica</i>
Impaired macrophage microbicidal function	<i>Leishmania</i> spp., <i>Trypanosoma cruzi</i> , <i>Trypanosoma brucei</i> , <i>Toxoplasma gondii</i> , <i>Entamoeba histolytica</i>
Impaired antigen presentation to T cells	<i>Leishmania</i> spp., <i>Trypanosoma cruzi</i> , <i>Toxoplasma gondii</i>
Synthesis of immunosuppressive mediators (e.g. IL-10, TGF- β , PGE ₂)	<i>Leishmania</i> spp., <i>Trypanosoma cruzi</i> , <i>Toxoplasma gondii</i> , <i>Entamoeba histolytica</i>
Generalized depression of T-cell responses	<i>Leishmania</i> spp., <i>Trypanosoma cruzi</i> , <i>Trypanosoma brucei</i>
Expansion of regulatory T-cell population	<i>Plasmodium</i> spp., <i>Leishmania</i> spp., <i>Trypanosoma cruzi</i>
Inhibition of phagolysosomal fusion	<i>Toxoplasma gondii</i>
Direct cytolysis of host inflammatory cells	<i>Entamoeba histolytica</i>
Degradation of host antibodies	<i>Entamoeba histolytica</i> , <i>Giardia lamblia</i> , <i>Trichomonas vaginalis</i>

Table 28.3 Principal mechanisms of innate and acquired immunity to protozoal pathogens

Immune mechanism	Pathogen
Innate immune response	
Complement-mediated lysis	<i>Plasmodium</i> spp., <i>Leishmania</i> spp.
IL-12-dependent NK-cell production of IFN- γ , leading to macrophage activation	<i>Plasmodium</i> spp. (pre-erythrocytic stage), <i>Leishmania</i> spp., <i>Trypanosoma cruzi</i> , <i>Trypanosoma brucei</i> , <i>Toxoplasma gondii</i>
Cross-reactive class II-restricted CD4 T cells	<i>Plasmodium</i> spp., <i>Toxoplasma gondii</i>
IFN- γ production by $\gamma\delta$ T cells	<i>Plasmodium</i> spp., <i>Toxoplasma gondii</i>
Activated polymorphonuclear leukocytes	<i>Leishmania</i> spp., <i>Entamoeba histolytica</i> , <i>Giardia lamblia</i> , <i>Trichomonas vaginalis</i> , <i>Cryptosporidium parvum</i>
Interferon- α/β activation of macrophages	<i>Leishmania</i> spp.
Antimicrobial peptides (defensins)	<i>Giardia lamblia</i> , <i>Cryptosporidium parvum</i>
Toll-like receptor signaling	<i>Plasmodium</i> spp., <i>Trypanosoma cruzi</i> , <i>Leishmania</i> spp.
Acquired immune response	
Parasite-specific IgG antibody response	<i>Plasmodium</i> spp., <i>Trypanosoma cruzi</i> , <i>Trypanosoma brucei</i> , <i>Giardia lamblia</i> , <i>Cryptosporidium parvum</i>
Class I-restricted, IFN- γ -producing CD8 T cells, which activate macrophage microbicidal mechanisms	<i>Plasmodium</i> spp., <i>Leishmania</i> spp., <i>Trypanosoma cruzi</i> , <i>Trypanosoma brucei</i> , <i>Cryptosporidium parvum</i>
Class I-restricted cytotoxic CD8 T cells	<i>Plasmodium</i> spp., <i>Leishmania</i> spp., <i>Trypanosoma cruzi</i> , <i>Trypanosoma brucei</i> , <i>Toxoplasma gondii</i> , <i>Entamoeba histolytica</i> , <i>Cryptosporidium parvum</i>
Class II-restricted, IFN- γ -producing CD4 T cells, which activate macrophage microbicidal mechanisms	<i>Toxoplasma gondii</i> (cyst stage), <i>Entamoeba histolytica</i> , <i>Giardia lamblia</i> , <i>Cryptosporidium parvum</i>
Mucosal IgA antibody response	

Fig. 28.1 Macrophage, NK cell and cytokine interactions in the innate immune response to intracellular protozoa. Exposure of macrophages or dendritic cells to a pathogen or microbial product can result in the release of cytokines and inflammatory mediators that may stimulate (+) or suppress (-) NK cell activation. Activated NK cells produce cytokines that can then activate macrophages for intracellular killing. It must be recognized that this diagram is oversimplified and that these cytokines, most notably IFN- α/β , IL-10, TGF- β , and IL-12, may be produced by other types of cell, such as epithelial cells or enterocytes. NO, nitric oxide; RNI, reactive nitrogen intermediates; ROI, reactive oxygen intermediates.

KEY CONCEPTS

IMMUNOPATHOGENESIS OF SEVERE *PLASMODIUM FALCIPARUM* MALARIA

- >> Release of malarial antigens stimulates TNF- α production.
- >> TNF- α induces expression of endothelial adhesion molecules (e.g. intercellular adhesion molecule-1, vascular cell adhesion molecule-1, thrombospondin, E-selectin, and chondroitin sulphate A).
- >> *P. falciparum* trophozoite proteins interact with the plasma membrane of the infected RBC to form knob-like protrusions and other membrane abnormalities.
- >> Infected RBCs with altered membrane surface adhere to upregulated endothelial adhesion molecules.
- >> Trapped infected RBCs are sequestered away from the splenic defense and cause microcapillary plugging, leading to inflammatory pathology and possible tissue ischemia.

GPI molecules also activate CD1d-restricted natural killer T (NKT) cells, leading to accelerated proinflammatory cytokine synthesis. T cells primed by previous exposure to either malaria or cross-reacting antigens also produce IFN- γ , which contributes to the production of a pathologically high level of TNF- α . Downregulation of the Th1 immune response and TNF- α production by IL-10 acts to limit the inflammatory response.

INNATE IMMUNITY

Complement-mediated lysis may occur at the sporozoite and merozoite stages. An IL-12 and IFN- γ -dependent pathway of innate resistance to exoerythrocytic stages of murine malaria has been identified. NK cells are probably the source of the IFN- γ .⁷ Although high levels of TNF- α are associated with severe malaria, physiological levels are protective through the activation of macrophages that can clear pre-erythrocytic-stage parasites.

The role of T cells in innate immunity to *Plasmodium* spp. is unclear. Malaria-reactive CD4 T cells, which express the $\alpha\beta$ TCR and are MHC class II restricted, have been identified in nonexposed individuals. Additionally, $\gamma\delta$ TCR⁺ T cells that respond to phosphorylated nonpeptide antigens on live parasites have been demonstrated. Both of these cell populations can secrete IFN- γ , and could therefore lead to phagocyte activation and killing of parasites.

ACQUIRED IMMUNITY

Partial immunity to *Plasmodium* spp. infection is acquired slowly following repeated exposure in endemic areas. In areas of intense *P. falciparum* transmission the density of parasitemia, the morbidity and the incidence of cerebral malaria and malaria-related deaths is highest in the early childhood years, declining thereafter.

Acquired immune mechanisms active at the pre-erythrocytic stage have largely been identified through studies in which mice were vaccinated with large numbers of irradiated sporozoites and challenged with murine *Plasmodium* spp. For reasons that are not clear, vaccination with sporozoites in experimental systems induces much stronger immunity than that induced by natural infection. Antibodies directed against a number of antigens expressed on the surface of the circulating sporozoite before it enters the hepatocyte are able to neutralize its infectivity. Anti-sporozoite antibody-mediated immunity requires the presence of high antibody titers to prevent sporozoite invasion of the hepatocyte, which occurs within minutes of inoculation. Acquired immunity to the pre-erythrocytic stage is mediated primarily through class I-restricted parasite-specific CD8 T cells, and to a lesser extent CD4 T cells, via secreted IFN- γ , which induces nitric oxide (NO)-dependent killing of the intra-hepatocyte parasites.⁸

Both antibody-dependent and cell-mediated (antibody-independent) immune mechanisms are active against the erythrocytic stage of infection.⁹ Immunity develops following drug-cured blood-stage infection in laboratory animals, and the immunity is stronger after repeated episodes of infection/cure. Adoptive transfer of antibodies from drug-cured mice confers protection to naïve mice. Similarly, adoptive transfer of immune human serum is protective for naïve individuals. Antibodies directed against merozoite surface proteins may inhibit invasion. The IgG₁ and IgG₃ isotypes play a role in naturally acquired immunity by opsonizing schizont- and trophozoite-infected RBCs (recognizing parasite antigens on the surface of the RBC) so that they can be cleared by phagocytic cells, especially in the spleen.

CD4 T cells are also able to confer immunity to blood-stage infection when adoptively transferred from immune mice. The mechanism(s) of CD4 T cell-mediated immunity is unclear, but MHC class II-restricted antigen presentation and T-cell co-stimulation are required, and the generation of cytokines and nitric oxide has been implicated in some studies. Protective cellular immune responses (CD4 and CD8 T-cell proliferation, IFN- γ production and NO synthesis) in the absence of detectable

antibody responses were identified in naïve volunteers who were repeatedly exposed to low doses of blood-stage parasites. T cells expressing the $\gamma\delta$ receptor have recently been shown to play a role in the control of chronic parasitemia in mice. The T-cell effector mechanisms that are active in acquired immunity to human malaria have not been defined.

EVASION OF HOST IMMUNITY

The malaria parasite uses several different mechanisms to evade the host immune response.⁵ Sporozoites and merozoites evade circulating antibody by rapidly entering hepatocytes or RBCs, respectively. Mature RBCs do not express MHC molecules on their surface, and so avoid recognition by T cells. The few parasite proteins that are expressed on the erythrocyte surface (e.g., *P. falciparum* erythrocyte membrane protein-1) exist in multiple allelic forms that have variable B-cell epitopes that induce only variant-specific antibody responses. Many of the immunodominant antigens in *Plasmodium* spp. are proteins having extensive repeat sequences that vary from strain to strain and tend to function as T-independent antigens that induce short-lived, low-affinity antibodies. Recently, CD4⁺CD25⁺ T-regulatory cells were shown to suppress antimalarial T-cell immunity in mice,¹⁰ possibly through the production of IL-10 and TGF- β . Both TGF- β , which can be converted from the latent to bioactive form by *Plasmodia* proteases, and IL-10 may suppress host effector mechanisms. The absence of these counter-regulatory cytokines leads to enhanced inflammatory pathology and mortality in rodent malaria models.

LEISHMANIA SPP.

PATHOGENESIS

The intracellular *Leishmania* amastigote replicates within macrophages in the vertebrate host, and the extracellular promastigote develops within the insect vector. The female phlebotomine sand fly becomes infected by ingesting amastigotes during a blood meal. In the sand fly gut the amastigotes differentiate into infectious metacyclic promastigotes that infect the vertebrate host during the next blood meal. The surface lipophosphoglycan (LPG) plays a central role in the parasite's entry and survival in host cells. Immunomodulatory factors present in the sand fly saliva may enhance the infectivity of the parasite.¹¹ Once introduced into the skin the promastigotes are phagocytosed (through complement-complement receptor-mediated coiling phagocytosis) by neutrophils, dendritic cells, and macrophages, where they transform to amastigotes and replicate within the acidic and hostile environment of the phagolysosome. Eventually the macrophages rupture and release amastigotes to infect other macrophages or a sand fly.

Tissue damage in the localized forms of leishmaniasis is mediated largely by an exuberant granulomatous response. In the case of localized cutaneous leishmaniasis (LCL) this response mediates parasite killing, so in most cases the tissue damage is short-lived and results in only a local scar. The extensive tissue destruction seen in mucosal leishmaniasis (ML) is mediated by a hyperreactive cellular immune response characterized by high levels of serum TNF- α and strong antigen-specific Th1 cytokine responses. An allelic association between ML and two different polymorphisms in the TNF- α and TNF- β genes has been described. Patients with diffuse cutaneous (DCL) and visceral leishmaniasis (VL) are anergic to *Leishmania* antigens, and the infection is relentlessly progressive.

INNATE IMMUNITY

Much of what we know of immunity in leishmaniasis comes from studies of inbred mouse strains, which demonstrate a genetically determined spectrum of innate and adaptive immune responses that determine the outcome of infection. The innate immune response to *Leishmania* is mediated by NK cells, cytokines and phagocytes. The production of IL-12 early in the course of infection, by dendritic cells but probably not by macrophages, leads to the early activation of NK cells and the production of IFN- γ . Chemokines (IP-10, MCP-1 and lymphotactin), as well as LPG-activated TLR4 on NK cells, can also promote early NK cell activation. Activated NK cells have been shown to be cytolytic for *Leishmania*-infected macrophages, but NK cell-derived IFN- γ plays a more prominent role in host defense by activating macrophages to kill the intracellular parasite through the generation of reactive oxygen intermediates (ROI) or reactive nitrogen intermediates (RNI). Parasite-induced MyD88-dependent signaling through TLR2, TLR3, and TLR4 contributes to macrophage activation and NO production. Activated polymorphonuclear leukocytes kill parasites primarily through oxidative mechanisms. IFN- α and IFN- β participate in the early induction of NO and control of parasite replication early in infection. The production of NO has a critical positive feedback effect on the IL-12-mediated NK-cell response.

ACQUIRED IMMUNITY

In an endemic area the prevalence of DTH skin test positivity increases and the incidence of clinical disease decreases with age, indicating the acquisition of immunity in the population over time. Retrospective epidemiological studies indicate that most individuals with prior (primary) infection (subclinical or healed) are immune to a subsequent clinical infection. Following primary infection parasites persist for the life of the host. In the murine model the persistence of parasites is required for the maintenance of long-term immunity.

There is extensive evidence from experimental models that cellular immune mechanisms mediate acquired resistance to *Leishmania* infection, and human studies have generally confirmed this.¹² Anti-leishmanial antibodies, which are produced at a low level in LCL and at a very high level in VL, play no role in protection. A high antibody level is a marker of progressive disease in VL, and in mice antibodies can promote IL-10 production and the maintenance of a Th2 response.¹³ Although there are some differences among the different *Leishmania* species, the general mechanisms of cellular immunity can be summarized (Fig. 28.2). Following infection in the skin, Langerhans' cells phagocytose and transport *Leishmania* to the regional lymph node, where they induce a T-cell response. Acquired immunity in murine cutaneous leishmaniasis caused by *L. major* is mediated by parasite-induced production of IFN- γ by CD4 T cells (Th1 subset). CD4 T cells are absolutely required, but immunity to cutaneous disease can develop in the absence of CD8 T cells. Both CD4 and CD8 T cells are required for an effective defense against murine visceral *L. donovani* infection, but the precise role of CD8 T cells is unclear. Generation of the Th1 response is critically dependent on CD40/CD40L-mediated IL-12 production and is driven by NK cell-derived IFN- γ . IL-27 plays a transient role in the development the Th1 response to *L. major* in some models, probably by counteracting the effects of early IL-4 production.¹⁴ IL-12 is required for the maintenance of immunity. Depletion of IL-12, or disruption of the

Fig. 28.2 Immunity in leishmaniasis. Exposure of dendritic cells to parasites or parasite antigens leads to the release of IL-12, which induces NK cells to produce IFN- γ and drives the acquired immune response toward a protective Th1 phenotype. IL-12 production by dendritic cells and IFN- γ production by NK and Th1 cells negatively regulates the Th2 response. IFN- γ activates macrophages to kill the intracellular pathogen. In genetically susceptible individuals a counter-regulatory Th2 cytokine response can suppress the Th1 response and deactivate infected macrophages, leading to parasite replication and uncontrolled infection. Counterprotective macrophage-derived cytokines can also inhibit the Th1 response, stimulate the Th2 response, and deactivate the macrophage through an autocrine loop. Activating stimuli are shown by solid arrows, and deactivating stimuli are shown by dashed arrows.

IL-12 gene, IL-18 gene or STAT4 gene (critical to IL-12 signaling), subverts Th1 cell development and renders resistant mice susceptible. Tumor necrosis factor- α (TNF- α) contributes to protective immunity by synergizing with IFN- γ to activate macrophages. Recently, NF- κ B family members have been shown to regulate T-cell responses and immunity to *L. major* infection in mice.

The generation of RNI by activated macrophages is the primary mechanism of parasite killing in the murine model.¹⁵ The Fas/Fas ligand pathway of CD4 T cell-induced apoptosis is also involved in the elimination of parasites. Although IFN- γ -induced production of NO may not be detectable in human macrophages, inhibition of nitric oxide synthase 2 (NOS2) was shown to impair killing of intracellular *Leishmania*.

Studies in the murine model of *L. major* infection have led to the idea that two populations of CD4 T cells mediate immunity induced by primary infection.¹⁶ Effector memory cells, which are short-lived and dependent on the persistence of antigen, respond rapidly to secondary infection by migrating to the infected tissue and generating effector cytokines. Central memory T cells, which can be maintained in the

absence of persistent antigen, circulate throughout the lymphatic system and upon secondary challenge migrate to and proliferate in the draining lymph node, gain the capacity to produce IFN- γ , and then migrate to the site of infection. Thus, central memory T cells act as a reserve of antigen-reactive T cells that can expand and become effector T cells in response to secondary antigenic challenge. There are a number of adaptive immune mechanisms that promote parasite replication and disease.¹⁷ The progression of murine *L. major* infection has been correlated with the expansion of Th2 cells and the production of IL-4, IL-5 and IL-10. In susceptible mice, IL-4 production within the first day of infection was shown to downregulate IL-12 receptor β -chain expression and drive the response to a Th2 phenotype. However, other nonsusceptible mouse strains appear to be able to overcome an early IL-4 response and develop a resistant phenotype, and susceptibility to some *L. major* strains is not strictly mediated by IL-4 (IL-13 may contribute). Additional factors, such as IL-10, TGF- β , or PGE₂, are required to maintain the Th2 response and the susceptible phenotype.¹⁶ Recent evidence indicates that susceptibility in the BALB/c mouse model of *L. major* infection is as much a result of an inherent defect in the Th1 development pathway and IL-10 production as it is related to the effects of IL-4.¹⁷ Besides inhibition of IFN- γ production, these factors suppress macrophage activation. The antigen-specific unresponsiveness of CD4 T cells during active VL is mediated in part by the engagement of the negative co-stimulatory receptor CTLA-4.

Peripheral blood mononuclear cells (PBMCs) isolated from patients with localized or subclinical leishmaniasis demonstrate a Th1 response to *Leishmania* antigens, and in general the intralésional cytokine profile is one of a dominant Th1 response. Patients with ML exhibit vigorous T-cell responses; it is postulated that this hyperresponsive state contributes to the prominent tissue destruction of ML. Patients with DCL resemble the progressive infection caused by *L. major* in BALB/c mice. Such patients demonstrate minimal or absent *Leishmania*-specific lymphoproliferative responses, and the Th2 cytokine mRNAs were prominently expressed in DCL lesions. During active VL in humans there is a marked depression of *Leishmania*-specific lymphoproliferative and IFN- γ responses, as well as an absence of DTH response to parasite antigens. This anergy appears to be mediated, at least in part, by a suppressive effect of IL-10 and low levels of IL-12. Successful treatment of active disease restores an antigen-specific Th1 response.

EVASION OF HOST IMMUNITY

The *Leishmania* parasite has numerous ways in which it adapts to and survives within the vertebrate host.^{15,17} In the skin the promastigotes are preferentially phagocytosed by macrophages that, unlike dendritic cells, do not actively participate in T-cell priming. The parasite's surface LPG (and to a lesser extent the surface protein gp63) plays an important role in the entry and survival of *Leishmania* in the mammalian host by conferring complement resistance, and by facilitating the entry of complement-opsonized parasites into the macrophage without triggering a respiratory burst. Macrophage phagosome-endosome fusion and phagolysosomal biogenesis are also inhibited by the parasite LPG.

Leishmania-infected macrophages have a diminished capacity to initiate and respond to a T-cell response, and the impaired antimicrobial effector activity provides a safe haven for the intracellular parasite.¹⁵ Infected macrophages have decreased synthesis of cytokines (IL-1, IL-12) and blunted IFN- γ -mediated activation (reduced MHC class II and

co-stimulatory molecule expression, and reduced production of ROI and RNI) through the disruption of signal transduction pathways involving JAK/STAT, protein kinase C, p38 MAPK, ERK, AP-1, and NF- κ B. Signaling mediated by tyrosine phosphorylation is reduced by the rapid induction of the host phosphotyrosine phosphatase SHP-1. Conversely, there is increased synthesis of the immunosuppressive molecules IL-10, TGF- β and prostaglandin E₂. Together these contribute to impaired antigen presentation to T cells. The IL-4/IL-13-enhanced expression of arginase by infected macrophages (termed alternatively activated macrophages) contributes to depletion of L-arginine and reduced NO production. Recently, IL-10-producing CD4⁺CD25⁺ T-regulatory cells at the site of chronic infection have been shown to play a role in the maintenance or progression of infection.¹⁸ IL-10 has an essential role in parasite persistence, as mice with IL-10 deletion or IL-10R blockade are able to eliminate the parasite.¹⁹

■ TRYPANOSOMA CRUZI ■

PATHOGENESIS

Trypanosoma cruzi is transmitted to the mammalian host when the infectious metacyclic trypomastigote, which is deposited on the skin in the feces of the reduvid insect vector while it takes a blood meal, is scratched into the wound or transferred to a mucous membrane (e.g., the eyes). The trypomastigotes can infect almost any cell type, and replicate as amastigotes in the cytoplasm. Eventually the amastigotes transform back into trypomastigotes and rupture the cell to enter the bloodstream, whence they invade other cells or are picked up by another insect vector.

Following primary infection the parasites replicate locally and then disseminate through the bloodstream to a variety of tissues. Muscle and glial cells are the most frequently infected, and acute myocarditis or meningoencephalitis can develop. In most cases, however, primary infection occurs without clinical symptoms and the infected individual may enter an indeterminate phase of asymptomatic seropositivity. Only 10–30% of chronically infected individuals will ultimately develop symptomatic Chagas' disease, usually involving the heart or gastrointestinal tract. Pathologically there are few parasites observed in cardiac tissue, but an intense chronic inflammatory infiltrate with fibrosis and loss of muscle fibers is evident. In the digestive tract there is lymphohistiocytic infiltration of the myenteric plexuses, with a dramatic reduction in the number of ganglion cells.

The tissue damage of acute *T. cruzi* infection is the result of a direct effect of the parasite and the acute host inflammatory response. In chronic infection the balance between immune-mediated parasite containment and host-damaging inflammation determines the course of disease. The pathological mechanisms related to chronic Chagas' disease are controversial, but whether tissue damage is caused directly by parasites or indirectly through parasite-directed inflammatory or autoimmune mechanisms, it is clear that parasite persistence is required for disease.^{20, 21} Autoimmunity could arise from molecular self-mimicry by parasite antigens, or by the release of self-molecules from damaged or dying host cells within the environment of an activated innate immune response. The production of IL-10 by *T. cruzi*-infected cells may downregulate the pathologic cellular immune response.²²

INNATE IMMUNITY

The early innate immune response to *T. cruzi* infection is mediated primarily by NK cells and macrophages.²⁰ Macrophages and DCs exposed to *T. cruzi* trypomastigote antigens produce proinflammatory cytokines, including IL-12 and TNF- α , through a MyD88-dependent mechanism. MyD88-deficient mice had impaired inflammatory responses and host defense against *T. cruzi*. IL-12 activates NK cells to secrete IFN- γ , which synergizes with TNF- α to activate macrophages to control parasite replication. The generation of NO is the primary trypanocidal mechanism in murine macrophages. A number of trypomastigote antigens, including free GPI anchors, glycoinositol phospholipids (GIPLs), GPI-linked glycoproteins, and GPI-mucins activate the innate immune response, at least partly through TLR-2.

ACQUIRED IMMUNITY

In infected mice the parasitemia (trypomastigotes) increases until 3–4 weeks after infection, when either the mice die or the infection is controlled by the acquired immune response. Antibodies contribute to immunity through opsonization, complement activation and antibody-dependent cellular cytotoxicity.

Several lines of evidence establish the importance of T cells in acquired immunity to *T. cruzi* infection. Parasite-specific CD4 and CD8 T cells are activated in response to infection, and mice lacking CD4 or CD8 T cells have impaired ability to control the infection. CD8 T cells with cytotoxic activity against *T. cruzi*-infected cells have been identified in infected mice, and these cells confer protection against challenge when passively transferred to naive mice. In the early stage of infection CD4 T cells are the predominant subset recruited to the myocardium, but activated CD8 T cells soon dominate the inflammatory process in cardiac tissue. Cytokine production (IFN- γ and TNF- α) by parasite-specific CD8 T cells is more important than cytolytic activity in the control of infection.²³

T. cruzi infection leads to a mixed Th1/Th2 cytokine response, and in general the Th1/Th2 balance determines resistance or susceptibility. As noted earlier, IFN- γ , produced in early infection by NK cells and later by T cells, clearly has an important protective function. Its protective effect is dependent on IL-12, as neutralization of IL-12 or deletion of STAT4 leads to increased parasitemia and earlier death, and the protection afforded to mice by the administration of IL-12 was abrogated by neutralization of IFN- γ and TNF- α . IL-4 does not appear to play a major role in susceptibility to *T. cruzi* infection, but IL-10 promotes parasite replication by inhibiting macrophage trypanocidal activity. IL-10 also plays a critical role in minimizing inflammation-mediated tissue pathology by regulating the Th1 and proinflammatory cytokine (predominantly TNF) responses.²² Similarly, TGF- β has been shown to inhibit macrophage trypanocidal activity and increase parasitemia and mortality. In addition to the production of these regulatory cytokines, the secretion of prostaglandins and NO, the induction of apoptosis of T and B cells, and the expansion of a myeloid suppressor cell population serve to control the intensity of the immune response.

EVASION OF HOST IMMUNITY

A significant part of the pathogenesis following *T. cruzi* infection is its dissemination through the bloodstream to many tissues. *T. cruzi* bloodstream trypomastigotes resist complement-mediated lysis because the parasite has

CLINICAL RELEVANCE

EVIDENCE FOR AUTOIMMUNE AND PARASITE-INDUCED INFLAMMATORY MECHANISMS IN CHRONIC CHAGAS' DISEASE

Evidence for autoimmune-mediated disease

Inflammatory disease is present in tissues with few or no parasites seen on routine histopathology studies.

There is a peculiar pattern of organ involvement (heart and gastrointestinal tract) in patients with chronic disease.

There is a long delay in the onset of chronic disease following infection, and only a minority of infected persons will ever develop disease.

There is wide variability in the expression of disease among infected people.

Self-reactive antibodies and T cells have been demonstrated in infected people and in experimental animals. The level of antibodies to the ribosomal P protein (R13 peptide) and cardiac myosin (B13 antigen) correlate with cardiac disease.

Transient or limited disease has been reported in experimental models following lymphocyte transfer.

Evidence for parasite-induced inflammatory disease

Sensitive parasite detection techniques (PCR, immunohistochemistry) show a strong correlation between the presence of parasites (or parasite material) and the severity of inflammatory disease.

Organs free of parasites (by sensitive parasite detection techniques) are also free of disease.

The absence of an effective cellular immune response (in mice or humans) almost invariably exacerbates rather than reduces the parasite burden and disease.

In chronically infected mice the destruction of a transplanted heart is dependent on parasite infiltrating the transplanted tissue.

The degree of disease in hearts transplanted into chronically infected mice correlates with the level of parasite burden in the transplanted tissue.

Reduction of the parasite burden by chemotherapy leads to decreased tissue inflammation and disease.

a complement regulatory protein (GP-160), which is functionally similar to mammalian decay-accelerating factor in that it inhibits C3 convertase formation and activation of the alternate complement pathway.

The establishment of chronic infection by *T. cruzi* is favored by a generalized depression of T-cell responses.²⁴ A number of different mechanisms may contribute to this, including low IL-2 production or IL-2 receptor expression; downregulation of components of the T-cell-receptor complex; T-cell receptor dysfunction; apoptosis of T cells; defects in the processing and presenting of antigens in the class II (but not the class I) pathway; T-cell or macrophage suppressor activity; and prostaglandin E₂ production.²⁵ Within foci of myocarditis, apoptosis of both parasites and host cells occurs; the phagocytosis of these apoptotic cells by macrophages leads to their deactivation or acquisition of an alternatively activated phenotype. Deactivated or alternatively activated macrophages may serve as an important host cell for parasite replication and persistence. The rapid escape of the parasite from the phagosome into the cytoplasm through the action of acid-activated porins enables the organism to avoid enzymatic destruction.

TOXOPLASMA GONDII

PATHOGENESIS

Transmission occurs via the ingestion of oocysts, which are shed in the feces of felines or present in undercooked meat. Following the oral ingestion of cysts, intestinal epithelial cells are infected by trophozoites that enter via the laminin receptor. The parasite transforms into intracellular tachyzoites that replicate within a parasitophorous vacuole and

ultimately rupture the cell. The released tachyzoites can invade virtually any nucleated cell type and disseminate to all tissues. Under pressure from the host immune response, tachyzoite replication is controlled and tissue cysts, which are a modified parasitophorous vacuole containing slowly replicating bradyzoites, are formed. The tissue cysts persist as a chronic latent infection as long as the host immune function is intact. The outcome of the host-parasite interaction is determined by the delicate balance between proinflammatory antimicrobial mechanisms and anti-inflammatory mechanisms that restrict tissue damage. If the latently infected person is immunosuppressed reactivation occurs, and tachyzoites are released to infect more cells. Because tissue cysts (bradyzoites) are found in proportionately larger numbers in the brain, reactivation of latent infection in the immunocompromised host is most commonly manifest as encephalitis.

INNATE IMMUNITY

Infection with *T. gondii* induces IL-12-dependent activation of NK cells. Activated NK cells produce IFN- γ , which in turn activates macrophages to limit parasite replication. Macrophage and dendritic cell production of IL-12 is enhanced by NK cell-derived IFN- γ . IL-12 production, which is essential to host resistance to *T. gondii*, is triggered through a MyD88-dependent mechanism, at least in part through the interaction of parasite-derived proteins and TLR11²⁶ and activation of CCR5. IL-12, IFN- γ , TNF- α and NK cells contribute to the control of the early stages of *T. gondii* infection in both immunocompetent mice and SCID mice (lacking T and B cells). The effects of IL-12 are augmented by other macrophage products, such as TNF- α , IL-1 and

IL-15. The early proliferation of NK cells is dependent on CD4 T-cell production of IL-2.

T cells expressing the $\alpha\beta$ T-cell receptor are also a source of IFN- γ early in the course of infection. In mice there is evidence that naïve T cells are activated through a superantigen-like effect, but the *T. gondii*-induced activation of T cells from previously unexposed human donors is dependent on the classic pathway of antigen processing and presentation (Chapter 6). T cells expressing the $\gamma\delta$ receptor are also an early source of IFN- γ and TNF- α , leading to macrophage activation and killing of *T. gondii*. $\gamma\delta$ T cells also induce macrophage heat-shock protein, which may prevent infected macrophages from undergoing apoptosis. In murine toxoplasmosis the virulence of *T. gondii* correlates with the ability of the parasite to induce macrophage apoptosis.

The mechanism(s) of IFN- γ -mediated macrophage activation for the control of early parasite replication is unclear. The production of NO by activated macrophages does not appear to play a significant role in the early stage of infection, but it is important in chronic infection. Other possible IFN- γ -dependent mechanisms that contain parasite replication include the generation of reactive oxygen intermediates and the limitation of intracellular tryptophan.

ACQUIRED IMMUNITY

The systemic antibody response does not play a role in acquired immunity to *T. gondii*. Mucosal IgA, however, does play a role in resistance to oral infection with *T. gondii* cysts. *T. gondii* is a potent activator of CD4 and CD8 T cells. The importance of T cells in acquired immunity to *T. gondii* is demonstrated by the following observations:²⁷ (1) athymic nude mice are highly susceptible to both virulent and avirulent strains of *T. gondii*; (2) depletion of T cells in chronically infected mice results in the reactivation of infection and death; (3) adoptive transfer of immune T cells confers protection on naïve mice against challenge with virulent parasites; (4) MHC class I and class II antigens have substantial influence on host resistance and susceptibility; and (5) patients with defects in T cell-mediated immune responses (e.g., patients with AIDS) are at risk for reactivation of latent infection.

NK cell-derived IFN- γ drives the differentiation of T cells into type 1 CD4 and CD8 T cells that are essential to acquired immunity. The route by which peptides enter the class I and class II antigen-processing pathways have not been fully defined, but evidence supports exogenous soluble antigens, perhaps derived from dead or dying parasites, as the source. Parasite-specific cytolytic T cells have been demonstrated in both murine and human infection. CD8 T cells are capable of transferring protection to naïve mice, primarily through the generation of IFN- γ ; the cytolytic activity of such cells is a secondary mechanism.²⁷ CD4 and CD8 T cells act synergistically to prevent cyst reactivation during chronic infection, and there is evidence that some human parasite-specific CD4 T cells have cytolytic activity. IL-27 negatively regulates T cell activation by a STAT1-dependent mechanism.¹⁴

Macrophage activation is the key effector mechanism in acquired immunity to *T. gondii*. In the case of murine toxoplasmosis, IFN- γ and TNF- α induce NO synthase and the production of reactive nitrogen intermediates. Neutralization of these cytokines leads to decreased expression of NOS2 and reactivation of chronic infection. As previously noted, the role of reactive nitrogen intermediates in the effector function of human macrophages is uncertain. Several other effector mechanisms,

including IFN- γ -mediated degradation of tryptophan, the generation of reactive oxygen intermediates and the production of leukotrienes, have been implicated in the control of *T. gondii* in human macrophages. Anti-inflammatory molecules, particularly IL-10, play an important role in modulating the adaptive immune response and restricting host tissue damage.²⁸ IL-10-deficient mice develop uncontrolled inflammation and tissue necrosis, which are mediated by overproduction of IFN- γ and TNF, leading to death.

EVASION OF HOST IMMUNITY

T. gondii escapes early macrophage killing in a number of ways.²⁸ Virulent parasites are protected by localization to the parasitophorous vacuole that does not fuse with host cell lysosomes, probably because the PV membrane proteins are of parasite rather than host origin and the vacuole is not acidified. The infected macrophage is also a suboptimal target for T cell-induced immunity because of reduced expression of MHC class II and co-stimulatory molecules. Infection also induces the production of counter-regulatory molecules, such as the cytokines IL-10 and TGF- β , an eicosanoid lipoxin A4, or members of the suppressor of cytokine synthesis (SOCS) family. These protect the host by downregulating a potentially pathologic inflammatory response, but also inhibit Th1 cytokine synthesis and macrophage antimicrobial activity. The production of oxide-reducing enzymes by the intracellular parasite can also neutralize effector molecules such as NO or superoxide.

■ ENTAMOEBA HISTOLYTICA ■

PATHOGENESIS

E. histolytica cysts are ingested through the consumption of food or water contaminated by feces. After excystation, the motile trophozoites penetrate the mucous barrier by mechanical disruption. The trophozoites adhere to the colonic epithelial cells by a galactose/*N*-acetylgalactosamine-inhibitable adhesin (Gal/GalNAc lectin). Epithelial cells with adherent amebae undergo shortening of microvilli and apical separation, and the trophozoites penetrate between the epithelial cells. This invasion is facilitated by cysteine proteases and a surface metallocollagenase, which attack the components of connective tissue ground substance causing ulceration of the colonic mucosa and submucosa (Fig. 28.3). The trophozoites of *E. histolytica* can lyse multiple cell types, including neutrophils, which release enzymes that further damage the tissue. The cytotoxic effects of amebae are mediated by a secreted cysteine protease, the Gal/GalNAc lectin, phospholipase A, and contact-dependent cytotoxicity, in which an ion channel (amebapore) is inserted into the membrane of target cells. *E. histolytica* can induce apoptosis in mammalian cells by a caspase-dependent, TNF- α /Fas-independent process. Amebic liver abscesses develop when trophozoites erode through the intestinal submucosa, enter the portal circulation and are deposited in the liver.^{29,30}

INNATE IMMUNITY

It is now thought that innate immunity is the key factor in the containment and resolution of amebic colitis.^{30,31} Trophozoites that successfully breach the protective mucous barrier bind to epithelial cells, stimulating the secretion of pre-IL-1 β , IL-1 α , IL-6, IL-8, GRO- α and GM-CSF,

Fig. 28.3 Immunopathogenesis of intestinal protozoal pathogens. After adherence (*Giardia* and *Entamoeba*) or epithelial invasion (*Entamoeba* and *Cryptosporidium*), there is release of various inflammatory mediators from macrophages and neutrophils. This causes the activation of resident phagocytes and recruitment of phagocytes into the lamina propria. Enterocyte death may be due to direct action of the parasites or to immune-mediated damage from complement, cytotoxic lymphocytes, proteases, and reactive oxygen and nitrogen intermediates (ROI and RNI, respectively). The inflammatory mediators also act on enterocytes and the enteric nervous system, inducing the secretion of water and chloride. Under the influence of activated T lymphocytes the response to enterocyte damage is that the crypts undergo hyperplasia and the villi become shorter (villous atrophy). The immature hyperplastic cells have poor absorptive ability, but retain secretory ability. Damage to the epithelium can cause leakage (exudation) from lymphatics and capillaries. Similar mechanisms are probably responsible for the diarrhea that occurs in infection with *Cyclospora* and *Isospora*. *Isospora* is unique in causing an eosinophilic infiltrate.

which attract leukocytes to the site of invasion.³² Neutrophils are the most important effector cells in clearing *E. histolytica* infection.³¹ Studies in IFN- γ receptor gene knockout mice suggest a role for IFN- γ in innate immunity against *E. histolytica*.³⁰

ACQUIRED IMMUNITY

Invasive amebiasis produces a humoral immune response in most patients, but the protection afforded is incomplete, i.e., an amebic liver abscess may progress despite an exuberant host antibody response. Nevertheless, antibodies protect against intestinal colonization and reinfection.⁴ The exact role of IgA in host defense against amebiasis is unclear; IgA deficiency does not cause more frequent or severe disease.³³

The role of cell-mediated immunity in the control of amebiasis is also not fully defined. Dissemination of infection occurs in some conditions where cell-mediated immunity is impaired,^{4, 33} but the AIDS epidemic has not resulted in an increase in cases of severe amebiasis. In rodents immunized with the Gal/GalNac lectin, or in humans who have antilectin antibodies, T lymphocytes produce IL-2 and IFN- γ when stimulated with one of the lectin's subunits. The Gal/GalNac lectin also triggers IFN- γ -primed macrophages to produce the

amebicidal molecule NO. Early amebic liver abscess in gerbils is associated with a mixed Th1/Th2 response, but with chronic infection the gerbils mount a Th1-like response. Gerbils cured of amebic liver abscess by antibiotic therapy likewise have a Th1 immune response and are resistant to reinfection.

EVASION OF HOST IMMUNITY

E. histolytica utilizes a number of strategies to circumvent the immune defenses of the host. It resists complement-mediated lysis during hematogenous spread by proteolytic degradation of C3 and C5. In addition, the Gal/GalNac lectin binds to C8 and C9, preventing assembly of the C5b-9 membrane attack complex⁴ (Chapter 20).

The cytolytic capability of *E. histolytica* affords protection from neutrophils, macrophages and eosinophils unless these cells are activated.³³ Cytolysis by *E. histolytica* may occur via necrosis and apoptosis; the use of the host's apoptotic machinery abrogates the local inflammatory response. Trophozoites also inhibit the macrophage respiratory burst and the production of IL-1 and TNF- α . A protective antibody response is subverted by the degradation of IgA and IgG by amebic cysteine proteases, and by capping, ingesting or shedding ameba-specific antibodies.³³

Amebic antigens may cause selective activation of Th2-type T cells, causing macrophage deactivation and anergy.⁴ Macrophages exposed to amebic lysates secrete prostaglandin E₂, which interferes with MHC II expression and TNF- α production. Patients with amebic liver abscesses have decreased CD4/CD8 T-cell ratios and decreased T-cell proliferation, which may be related to reduced IL-2 production.

■ GIARDIA LAMBLIA ■

PATHOGENESIS

After ingestion of the *Giardia* cyst in fecally contaminated food or water, excystation occurs, with the release of trophozoites. The trophozoites multiply in the small bowel. As they transit through the lower intestine they encyst, allowing the organism to survive in the environment and to be transferred to another host. The *Giardia* trophozoite initially adheres to intestinal epithelium via a surface mannose-binding lectin. Histopathologic changes in symptomatic giardiasis range from a normal appearance to villous atrophy, crypt hyperplasia, epithelial damage, and chronic inflammatory infiltrate in the lamina propria (Fig. 28.3). The factors responsible for the structural changes in the small bowel are not well defined, but may include injury from adherence, and the release of cytotoxins, including proteases. Furthermore, epithelial damage may be mediated by the host cellular immune response.³⁴

INNATE IMMUNITY

Giardia has a limited capacity to neutralize reactive oxygen species, which are produced by intestinal epithelial cells. The antimicrobial peptide defensin is produced by Paneth cells and thus may also participate in host defense against *Giardia*. Few macrophages are found in the intestinal mucosa during giardiasis, which suggests they do not play an important role in the innate immune response.³⁵ The infection is rare in breastfed infants because breast milk contains free fatty acids lethal to *Giardia* cysts and, in endemic areas, anti-*Giardia* antibodies.³⁴

ACQUIRED IMMUNITY

Several lines of evidence suggest the importance of the humoral immune response in the control of giardiasis.³⁵ Infection with *Giardia* results in the production of anti-*Giardia* antibodies in the serum and mucosal secretions. Human immunodeficiency syndromes that affect antibody production are associated with chronic giardiasis.

There is evidence for a role of T cell-dependent immunity in the control of giardiasis, but the mechanisms of immunity have not been fully defined.³⁵ T cell-deficient mice and mice treated with anti-CD4 antibody are unable to control *Giardia* infection. CD8 T lymphocytes are not important in protective immunity.

EVASION OF HOST IMMUNITY

Giardia undergoes surface antigenic variation by altering a group of variant-specific surface proteins (VSPs). Selection occurs by an immune-mediated process, because switching occurs when intestinal anti-VSP IgA responses are first detected.³⁶ *Giardia lamblia* also produces a protease that cleaves IgA.

■ CRYPTOSPORIDIUM PARVUM ■

There are three intestinal coccidian parasites of humans that are intracellular parasites of enterocytes: *Cryptosporidium parvum*, *Isospora belli* and *Cyclospora cayentanensis*. *Cryptosporidium* has the greatest epidemiologic significance: in 1993 a huge outbreak involving 403 000 persons occurred in Milwaukee, Wisconsin.³⁷ Because of their similarity, only the immunology of cryptosporidiosis will be discussed in detail.

PATHOGENESIS

Infection with *Cryptosporidium* occurs when sporulated oocysts are ingested and excyst in the proximal small bowel, invade the intestinal epithelial cells (facilitated by a cysteine protease), develop into trophozoites and undergo schizogony, with a resultant merozoite-containing schizont. The merozoites are extruded and invade other epithelial cells. The merozoites may continue an asexual cycle or develop into macro- or microgametes that fuse to form oocysts.

Histologically, in the infected small bowel there is villous atrophy and blunting, and crypt hyperplasia with increased infiltration of lymphocytes, macrophages and plasma cells. Intraepithelial lymphocytes are uncommon; neutrophils and occasional eosinophils are present between the epithelium and the lamina propria. Disorganized cells undergoing necrosis replace normal enterocyte architecture (Fig. 28.3). There is an association between the degree of intestinal injury and malabsorption and the intensity of infection, as measured by oocyst excretion.³⁷

INNATE IMMUNITY

Knowledge of the immune response to cryptosporidiosis has been hampered owing to the lack of experimental models of infection. Acute infection in an immunocompetent mouse older than 3 weeks is difficult to establish, so the neonatal mouse model has been most commonly studied. The increased susceptibility of neonates (including humans) may be related to an undeveloped IL-12-dependent IFN- γ pathway.

Because of the parasite's intracellular location near the luminal surface of the enterocyte, the macrophages of the lamina propria are spatially isolated from the parasite. Thus, the intestinal epithelium mounts its own assault on the invading microbe by the activation of NF- κ B and the release of TNF- α and the chemokines IL-8, RANTES, and GRO- α , which act as chemoattractants and activators of neutrophils.³⁸ TNF- α also inhibits parasite replication. Infected epithelial cells may attempt to eliminate the parasite through apoptosis;³⁸ however, NF- κ B activation protects the infected epithelial cells from apoptosis, thereby facilitating parasite survival and replication.³⁹

Infected intestinal cells also release TGF- β , which decreases necrosis and stimulates the synthesis of extracellular matrix proteins, which limit epithelial damage.³⁸ Antimicrobial peptides (the defensins) released by intestinal cells also have anti-cryptosporidial activity. There are contradictory data on the role of NO in the control of cryptosporidiosis.³⁸

ACQUIRED IMMUNITY

The relative contribution of antibody responses to the control of cryptosporidiosis is uncertain.³⁹ The enterocyte membrane enveloping the parasitophorous vacuole contains *C. parvum* antigens that are recognized

by antibody. Serum and mucosal antibody responses accompany resolution of the diarrhea and oocyst shedding, and may contribute to resistance to, or decreased severity of, reinfection.

CD4 T cells play a central role in the control of cryptosporidiosis. Mice that lack CD4 T cells experience persistent infection. In patients with AIDS, severe disease or biliary involvement (an indicator of chronic infection) is usually seen in those with CD4 counts $<50/\text{mm}^3$. HIV-infected patients with CD4 counts >200 usually experience only transient disease. In contrast, peripheral CD8 cells have only a minor role in the immune response. Adoptive transfer of intraepithelial lymphocytes (IELs) from *C. muris*-immune BALB/c mice results in parasite clearance in SCID mice.³⁹ In immunocompetent mice CD4 IELs increase and initiate early control of infection, whereas cytotoxic CD8 IELs appear later and function in parasite elimination.⁴⁰ In murine models, both CD4 cells and IFN- γ of T- and non-T-cell origin are necessary to prevent or limit the severity of infection. In IFN- γ -deficient mice infection with *C. parvum* leads to mucosal destruction, rapidly progressive wasting and death. However, in humans, IFN- γ may not play a major role in controlling primary infection, but may be more relevant to the control of infection in previously exposed individuals.³⁹

Recently, a role for $\gamma\delta$ T cells in host defense against *C. parvum* has been recognized. These cells are rapidly recruited to the site of cryptosporidial infection, and deficiency leads to increased susceptibility to infection in mice. The role of $\gamma\delta$ T cells in the human immune response in cryptosporidiosis is unknown.³⁸ IL-15 may be involved in the control of primary infection in naïve human hosts by the activation of $\gamma\delta$ T cells, NK cells, and perhaps enterocytes.³⁹

The role of CD154–CD40 interaction in the control of *C. parvum* infection has recently been elucidated. CD154 is a TNF-like molecule expressed on the surface of activated CD4 cells. CD154 binds to CD40, which is expressed on B cells, macrophages, dendritic cells, epithelial cells, and T cells. The interaction stimulates the production of IL-12, IFN- γ , and NO, and induces apoptosis in infected cells. Knockout of these molecules results in persistent infection.³⁹

TRICHOMONAS VAGINALIS

PATHOGENESIS

Trichomonas vaginalis is a flagellated protozoan parasite of the human urogenital tract that exists only as a trophozoite. Its adherence to the vaginal squamous epithelium is facilitated by a number of adhesins. *Trichomonas* causes tissue damage by contact-dependent cytolysis due to pore-forming proteins and proteases, and secretion of a glycoprotein cell-detaching factor that causes sloughing of the vaginal epithelium. Levels of the cell-detaching factor correlate with the severity of the disease, and vaginal antibodies directed against this factor modulate its effects. Inflammation in the genital mucosa and submucosa leads to copious secretions, and the surface epithelium may slough, causing focal erosions and hemorrhage.

The increased risk of HIV transmission in women with trichomoniasis may be due to increased recruitment of inflammatory cells, mucosal erosion, or degradation of secretory leukocyte protease inhibitor (SLPI) by trichomonal proteases. Lower levels of SLPI are found in the vaginal fluid of women with trichomoniasis, which can lead to increased tissue damage and HIV transmission.⁴¹

INNATE IMMUNITY

Although trichomoniasis has recently received increased attention as a risk factor for HIV transmission and obstetric complications, there is little known about the protective immune response against this organism. *Trichomonas* secretes a factor that promotes neutrophil chemotaxis, causing profuse leukorrhea, but the oxidative microbicidal mechanisms of the neutrophils have decreased efficacy in the anaerobic vaginal environment.⁴² Macrophages can destroy trichomonads in a T and B cell-independent manner.

ACQUIRED IMMUNITY

Repeated infections with *T. vaginalis* do not induce immunity; however, the infection is self-limiting in most cases, so there are mechanisms of host defense. *T. vaginalis* induces the production of antibodies in both the serum and vaginal secretions. The serum antibody response correlates with active infection, and serum, but not vaginal, IgG from infected patients displays complement-mediated lytic activity against trichomonads in culture.⁴³

EVASION OF HOST IMMUNITY

Although *T. vaginalis* activates the alternative pathway of complement, the cervical mucus and menstrual blood are low in complement. Menstrual blood also supplies iron, which upregulates trichomonal adhesins and cysteine proteases, causing the degradation of complement component C3 bound to the surface of the parasite. Parasite virulence is thus enhanced, and the symptoms are exacerbated during menses. Cysteine proteases secreted by *T. vaginalis* also degrade immunoglobulins, sabotaging the antibody response. The parasite also secretes soluble antigens that act as decoys for neutralizing antibodies or cytotoxic T cells, and disguises itself by binding to host plasma proteins. Phenotypic variation of surface markers is also a means of antibody evasion.⁴³

Immune responses to helminths

Subash Babu, Thomas B. Nutman

29

Parasitic helminths are complex eukaryotic organisms characterized by their ability to maintain long-standing chronic infections in human hosts, sometimes lasting decades. Hence, parasitic helminths are a major health care problem worldwide, infecting more than 2 billion people, mostly in developing countries (Table 29.1). Common helminth infections, such as intestinal helminths, filarial and schistosome infections, are a major medical, social, and economic burden to the countries in which these infections are endemic. Chemotherapy, while highly successful in some areas, still suffers from the disadvantages of the length of treatment, the logistics involved in the distribution of drugs and, in some cases, the emergence of drug resistance. Vector control measures are at best an adjunct measure in the control of helminth infections but also suffer from the same social, logistic, and economic obstacles as mass chemotherapy. Therefore, the study of the immune responses to helminth infections attains great importance both in terms of understanding the parasite strategies involved in establishing chronic infection and in the delineation of a successful host immune response to develop protective vaccines against infection.

SPECTRUM OF HOST-PARASITE INTERACTIONS

While both protozoa and helminths can cause parasitic infections, the biology and the host response to each are extremely different. Protozoa are small unicellular organisms that multiply intracellularly and pose an extreme immediate hazard to the host immune system. Helminths, in contrast, are large (often centimeters to meters in length), extracellular (the exception being *Trichinella spiralis*), and typically do not multiply in their vertebrate host and therefore do not present an immediate threat during initial infection.

Helminths have characteristically complex lifecycles with many developmental stages. Thus, the host is exposed during the course of a single infection to multiple lifecycle stages of the parasites, each stage with both a shared and a unique antigenic repertoire. Thus, in *Schistosoma mansoni*, infection begins with penetration of the skin of humans exposed to infested waters by the free-swimming cercariae, which then develop

into tissue-dwelling schistosomula. In the liver and mesenteric veins, schistosomula differentiate into sexually dimorphic adult worms which mate and the resultant eggs migrate through tissues into the lumen of the intestine or bladder for environmental release. Similarly, in lymphatic filarial infection, the host is exposed to the infective-stage larvae in the skin, lymph nodes, and lymphatics, to the adult worms in the lymph nodes and lymphatics, and finally to the microfilariae in the peripheral circulation. Hence, the host-helminth interaction is complex not only due to the multiple lifecycle stages of the parasite but also because of the tissue tropism of the different stages.

Antigenic differences among the lifecycle stages can lead to distinct immune responses that evolve differentially over the course of a helminth infection. In addition, depending on the location of the parasite, the responses are compartmentalized (intestinal mucosa and draining lymph nodes in intestinal nematode infection or skin/subcutaneous tissue and draining lymph nodes in onchocerciasis) or systemic (lymphatic filariasis or schistosomiasis). Moreover, the migration patterns of the parasite might elicit varied cutaneous, pulmonary, and intestinal inflammatory pathologies, as seen, for example, in *Ascaris* or *Strongyloides* infection during their migratory phase. This is further complicated by the fact that human hosts are often exposed to multiple lifecycle stages of the parasite at the same time. Thus, a chronically infected patient with lymphatic filariasis harboring adult worms and microfilariae might be exposed to insect bites transmitting the infective-stage parasite. The immune response that ensues will not only be a reaction to the invading organism but will also bear an imprint of the previous exposures and the concurrent infection.

Helminth infections can elicit a spectrum of clinical manifestations mirroring diversity in host immune responses. For example, in lymphatic filariasis, most infected individuals remain clinically asymptomatic despite harboring significant worm burdens felt to reflect the induction of parasite-specific tolerance in the immune system. Others exhibit acute manifestations including fever and lymphadenopathy that are felt to reflect inflammatory processes induced by incoming larvae, dying worms, or superadded infections. Individuals who mount a strong but inappropriate immune response end up with lymphatic damage and subsequent immune-mediated pathology – hydrocele and elephantiasis. Finally, a group of infected individuals mount exuberant immune responses, often

Table 29.1 Prevalence and distribution of common helminth infections

Types of helminths	Numbers infected (million)	Distribution
Intestinal helminthes		
<i>Ascaris lumbricoides</i>	1221	Worldwide
Hookworm spp. ^a	740	Worldwide
<i>Strongyloides stercoralis</i>	75	Worldwide
<i>Trichuris trichiura</i>	795	Worldwide
Schistosomes		
<i>Schistosoma mansoni</i>	67	South America, Africa
<i>Schistosoma japonicum</i>	1	Eastern Asia
<i>Schistosoma haematobium</i>	119	Africa
Filarial parasites		
<i>Onchocerca volvulus</i>	37	Africa, Central and South America
<i>Wuchereria bancrofti</i>	120	Worldwide
<i>Brugia malayi</i>	10	Asia
<i>Loa loa</i>	13	Africa
Animal parasites^b		
<i>Taenia solium</i>	1	Worldwide
<i>Echinococcus granulosus</i>	1.5	Worldwide
<i>Toxocara canis</i>	7	Worldwide

^aBoth *Necator americanus* and *Ancylostoma duodenale*.
^bThese are characteristically parasites of animals that infect humans incidentally but cause serious diseases such as cysticercosis, hydatid disease, and visceral larva migrans.

KEY CONCEPTS**HELMINTH INFECTION**

- >> Divided into nematodes, trematodes, and cestodes
- >> Produce chronic infections that can persist for decades
- >> Characteristically cause morbidity rather than mortality
- >> Multicellular parasites that do not multiply in the definitive host but can reproduce sexually to produce larval stages that ensure continued transmission

resulting in unusual pathology such as tropical pulmonary eosinophilia. Thus, the clinical manifestations of lymphatic filariasis exemplify the spectrum of host–parasite interactions that occur during helminth infections (Fig. 29.1).

Another hallmark of all helminth infections is their chronicity, with many helminths surviving in the host for decades. For example, adult schistosomes and filariae may survive in host tissues for as long as 30 years, producing eggs and larval stages throughout most of their lifespan. Similarly, *Strongyloides stercoralis* due to its ability to ‘autoinfect’ can

maintain its lifecycle indefinitely. Chronic infections certainly reflect an adaptation that leads to ‘parasitism’ since inducing mortality would prevent parasite transmission if the hosts were to die before larval release or egg production could occur. In addition to the long-lived nature of the infection, helminths frequently induce a harmonious host–parasite interplay so that relatively asymptomatic carriers are available as reservoirs for ongoing transmission. Of course failure to establish the harmonious coexistence does occur in certain cases, leading to severe pathology exemplified by cirrhosis and portal hypertension in schistosomiasis and elephantiasis associated with lymphatic filariasis.

■ PROTOTYPICAL HOST RESPONSES TO HELMINTHS ■

The discovery by Mosmann et al.¹ that fully differentiated mouse CD4 T cells tend to polarize into two different subsets based on their cytokine secretion patterns – Th1 cells secreting interleukin-2 (IL-2) and interferon- γ (IFN- γ) and Th2 cells secreting IL-4 and IL-5 – has been repeatedly confirmed in studies employing both *in vitro* and *in vivo* systems. Infection with the intracellular protozoan parasite, *Leishmania major* resolves in mice that mount Th1 responses but is exacerbated in mice making a Th2 response. Th1 responses were subsequently

Fig. 29.1 The clinical manifestations of lymphatic filariasis, including: (A) mild lymphedema; (B) severe lymphedema; (C) elephantiasis; and (D) hydrocele.

demonstrated to include tumor necrosis factor- β (TNF- β) and Th2 responses – IL-9 and IL-13. This polarization is driven by the cytokine environment in which CD4 T cells differentiate, thus IL-12 and, to a lesser extent, IL-23 are known inducers of Th1 responses while IL-4 is a potent inducer of Th2 responses.² Dendritic cells (DC) and macrophages, both professional antigen-presenting cells, are the major sources of IL-12, while differentiated T cells, natural killer (NK) T cells, eosinophils, basophils, and mast cells are sources of IL-4. More recently, the transcriptional mechanism that governs Th1/Th2 differentiation has been elucidated. The transcription factor T-bet is essential for Th1 differentiation, whereas the transcription factor GATA-3 is crucial for Th2 differentiation. These transcription factors and polarizing cytokines are known to cross-regulate each other; thus both T-bet and GATA-3 suppress the induction of the other and IFN- γ and IL-4 are mutually antagonistic.

The immunological hallmark of helminth infections is their ability to induce Th2 responses characterized by the presence of IL-4, IL-5, IL-9, IL-10, and IL-13, generalized eosinophilia, goblet and mucosal mast-cell hyperplasia, and production of immunoglobulin E (IgE) and IgG₁ (in mice) and IgE and IgG₄ (in humans).³ While the Th2 response induced by helminth parasites is a stereotypical response of the host, the initiation, progression, and culmination of this response require interaction with many different cell types, most notably: (1) antigen-presenting cells – DC and macrophages; (2) T cells; (3) B cells; (4) eosinophils; and (5) mast cells and basophils. In addition, the host–helminth interactions lead to a variety of modulated immune responses such as the

induction of regulatory T cells and alternatively activated macrophages (Fig. 29.2).

HELMINTHS AND DENDRITIC CELLS

DC are professional antigen-presenting cells that play an essential role in presenting antigen to T cells to initiate immune responses. For Th1 responses, DC present bacterial or protozoan antigens in the context of upregulated co-stimulatory molecules – CD80 and CD86; Th1 biasing pattern recognition receptors such as Toll-like receptors (TLRs: most notably); and of the presence of IL-12.⁴ However, very little is known about the role of DC in the initiation of Th2 responses, as occurs in helminth infections. It has been shown that differentiation and maturation of DC in the presence of helminth antigens can lead to robust Th2 responses with inhibition of IL-12 production.⁴ This has been demonstrated using: (1) excretory-secretory products from *Acanthocheiloneuma viteae* and *Nippostrongylus brasiliensis*, both rodent filarial parasites; (2) *Schistosoma mansoni* soluble egg antigen or the schistosomal glycan lacto-N-fucopentose III or double-stranded RNA; and (3) live microfilariae from *Brugia malayi*.⁵ Although NF- κ B1 activation has been found to be required for DC-mediated Th2 differentiation in helminth infections, the nature of the receptors and other signaling molecules involved is not yet known. Finally, it has been shown that helminth parasites can interact directly with TLRs on DC, either through TLR2 (for schistosomes and filariae) or TLR4 (for the filarial parasites). The modulation of DC function by helminth antigens appears to be generalizable and has been

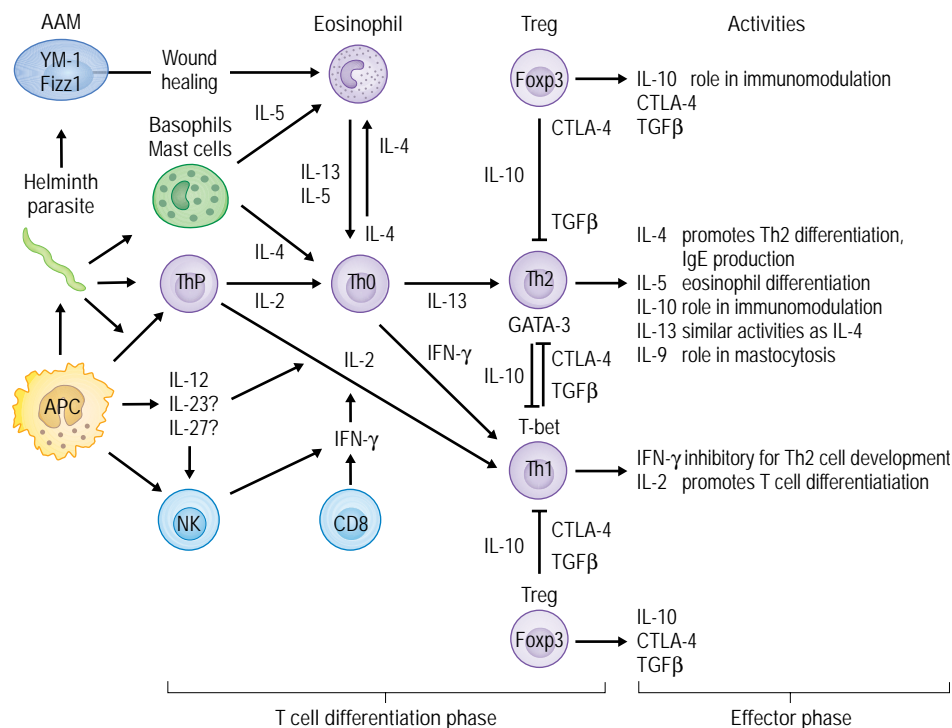

Fig. 29.2 Regulation of the T-cell response in helminth infection. AAM, alternately activated macrophages; APC, antigen-presenting cell; IFN, interferon; IL, interleukin; Th, T helper; Thp, precursor T cell; Treg, regulatory T cells.

shown to impair their ability to respond to other infectious stimuli (e.g., *Mycobacterium tuberculosis*).⁶

HELMINTHS AND MACROPHAGES

Macrophages are the other important class of antigen-presenting cells that can serve as protective effector cells in bacterial and protozoan infections by their production of nitric oxide and other mediators. Helminth interaction with macrophages induces a population of macrophages preferentially expressing arginase instead of nitric oxide due to increased activation of arginase-1 by IL-4 and IL-13. These macrophages, termed alternatively activated macrophages, are characterized by their ability to upregulate YM-1 and Fizz-1, two gene products whose function remains unknown.⁷ These alternatively activated macrophages are known to be important in wound healing and have been postulated to play a potential role in repairing wound damage that occurs during tissue migration of helminth parasites. In addition, these macrophages mediate a hyporesponsiveness in cognate T cells and play an additional role in the modulation of the immune responses. While helminth infection does induce expression of these cells in humans, early interaction of parasites or parasite antigens leads to a predominantly proinflammatory response with expression of TNF- α , IL-6, IL-1 β , MIP-1 β , MIP-3 β , IL-8 as well as CD44 and ICAM-1, genes involved in inflammation and adhesion.⁸ Chronic infection then results in macrophages with downregulatory activity, as evidenced by the production of IL-10 and transforming growth factor- β (TGF- β), both potent depressants of T-cell activity.⁵

HELMINTHS AND T CELLS

Typically, acute infections with tissue-invasive helminths induce a robust Th2 response manifested by enhanced expression of IL-4, IL-5, and IL-13 in response to live parasites, parasite antigens, or mitogens.⁵ The Th2 bias is often antigen-specific but in some cases bystander spillover can lead to Th2 responses to nonparasite antigens.⁵ There are however exceptions to this canonical Th2 response to helminth infections. Immune responses to schistosome cercariae are Th1 in nature and only upon egg-laying does a Th2 response emerge. Early immune responses of unexposed individuals to live filarial parasites are markedly Th1-like and in murine infections microfilariae of *B. malayi* promote Th1 responses. Finally, immune responses to the gut nematode *Trichuris muris* can be Th1 or Th2 depending on the mouse strain used for infection. Since the establishment of Th2 responses requires early induction of IL-4, one of the major research topics in helminth immunology has been on the identification of the source of this early IL-4. Depending on the model system used, it has been determined that basophils, NKT cells, and eosinophils can all serve as the early sources of IL-4 for Th2 differentiation in helminth infection. In addition to the early expression of IL-4, other factors, including expression of co-stimulatory molecules on naïve T cells, have been shown to play an important role in Th2 differentiation.⁹ Thus, CD80, CD86 interaction with CD28 and ICOS-ICOS ligand as well as OX40-OX40 ligand interaction have been shown to be useful in the initiation or maintenance of the Th2 response. In addition, interaction of the Notch receptor with its ligand, Jagged, is known to induce Th2 differentiation. Finally, induction of GATA-3 and downregulation of T-bet has been shown to be an important step in T-cell differentiation to the Th2 phenotype in helminth infections.¹⁰

Interestingly, chronic helminth infections are associated with a downmodulation of parasite antigen-specific proliferative responses as well as IFN- γ and IL-2 production but with intact IL-4 responses to parasite antigens and global downregulation of both Th1 and Th2 responses to live parasites.¹¹

HELMINTHS AND B CELLS

Helminth interactions with B cells occur both at the B-cell cytokine level and at the level of antibody production. Interactions at the cellular level primarily result in B-cell activation and cytokine production, most notably IL-10. Also, B-cell production of IL-4 has been demonstrated in mouse models of helminth infection. However, it is at the level of antibody production that B cells play a profound role in helminth infections. One of the most consistent findings in helminth infections, both in mice and humans, is the elevated level of IgE that is observed following exposure to helminths. Most of the IgE produced is not antigen-specific, perhaps representing nonspecific potentiation of IgE-producing B cells or deregulation of a normally well-controlled immune response. This potentiating effect seems to be selective for IgE (and possible IgG₄). Elevated levels of total serum IgE have been documented in many studies. Characteristically, individuals with invasive helminth infections have serum IgE levels approaching 100 times normal value. In addition, the IgE antibodies have specificity against a very broad range of parasite antigens. Interestingly, these IgE antibodies persist many years after the infection has been treated, indicating the presence of long-lived memory B cells or plasma cells in helminth infections.¹² IgE production in both mice and humans is absolutely dependent on IL-4 or IL-13. Other isotypes that are commonly elevated in chronically helminth-infected humans are IgG₄ and IgG₁, the former being most dependent on both IL-4 and IL-10.¹³

HELMINTHS AND EOSINOPHILS

Blood and tissue eosinophilia is characteristic of helminth infection and is mediated by IL-5 (typically in concert with IL-3 and granulocyte-macrophage colony-stimulating factor). Recruitment of eosinophils to the site of infection occurs very early in experimental helminth infection – as early as 24 hours following exposure. Kinetics in humans is harder to determine but is postulated to occur as early as 2–3 weeks following infections, as demonstrated in experimental infections of volunteers. Apart from the rapid kinetics of recruitment, eosinophils in the blood and tissue also exhibit morphological and functional changes attributable to eosinophil activation. These include decreased density, upregulation of surface activation molecules such as CD25, CD69, CD44, and HLA-DR, enhanced cellular cytotoxicity, and release of granular proteins, cytokines, leukotrienes and other mediators of inflammation.¹⁴ Activation of eosinophils requires T cells since, in the absence of T cells, eosinophils accumulate at the site of infection but do not degranulate or become cytotoxic.

HELMINTHS AND BASOPHILS/MAST CELLS

Basophils are an important component of the immune response to helminth infections. Basophilia occurs in several animal models of helminth infections (not however in humans) and basophils can release IL-4 and histamine in response to parasite antigen stimulation. Moreover,

basophils have the capacity to release large amounts of IL-4 and IL-13 rapidly, within minutes of surface IgE cross-linking. Basophils have been shown to be a major source of IL-4 and to accumulate in tissues in helminth infections, thereby contributing to both the initiation and maintenance of antigen-specific Th2 responses. In addition, *S. mansoni* eggs are known to contain a factor, termed IL-4-inducing principle of *S. mansoni* eggs or IPSE, that has been shown to induce IL-4 release from human basophils in a non-IgE-dependent manner.

Mast cells may also contribute to inflammatory reactions directed against invasive helminth parasites. These cells express high-affinity Fcε receptors that are sensitized with parasite antigen-specific IgE and which can be triggered by parasite antigens. It has been postulated that cytokines and other mediators released by sensitized mast cells contribute to: (1) the recruitment and activation of effector eosinophils; (2) increased local concentrations of antibody and complement; and (3) mucus hypersecretion and increased peristalsis of the gastrointestinal tract that plays an important role in resistance to certain gastrointestinal nematode infections.¹⁵

■ PROTECTIVE IMMUNITY AGAINST HELMINTHS ■

SUSCEPTIBILITY TO HELMINTH INFECTION

Multiple factors have been shown to play a role in susceptibility to helminth infection, including age, sex, and genetics. Most helminth infections are acquired relatively early in life and resistance to infection or reinfection develops with increasing age and exposure. Interestingly, gender also plays an important role in susceptibility, with males – both humans and mice – being more susceptible to some but not all helminth infections. In addition to prevalence, the intensity of infection is also higher in males. This trend might be the result of either innate male susceptibility or behavior-related increases in exposure to parasites. Moreover, animals housed in controlled conditions also exhibit this gender dichotomy, implicating host male physiology as a contributing factor to this phenomenon. Several studies link gender differences in immunological function to circulating hormones, such as testosterone, estradiol, and progesterone, as well as glucocorticoids. Finally, a genetic predisposition to innate resistance to parasitic helminths is also considered to be a factor, with major histocompatibility complex (MHC) genes playing an important role in susceptibility to infection.

EVIDENCE FOR PROTECTIVE IMMUNITY IN HUMANS

Although acquired immunity is difficult to demonstrate definitively in many helminth infections, three important lines of evidence for the presence of acquired, immunologically mediated resistance exist. First, epidemiologic studies (flattening of age prevalence curves) suggest that in schistosomiasis and in all the filarial infections, resistance occurs and is acquired with increasing age. Second, a phenomenon known as concomitant immunity, resistance to reinfection in the presence of ongoing infection, has also been demonstrated to exist in helminth infections. Finally, a genetic predisposition to mounting an effective immune response has been suggested and linkage mapping techniques are now being utilized to map quantitative trait loci (QTL) associated with resistance to helminths using microsatellite markers.¹⁶ Indeed, QTL analysis has shown that the intensity of intestinal

helminth infection is a heritable phenotype and that the proportion of variance in human worm intensity influenced by genetic effects varies from 0.21 to 0.44. In schistosomiasis, anti-infection immunity is dependent on Th2 cells and is controlled by a major genetic locus located on chromosome 5q31-33. In contrast, protection against disease (e.g., hepatic fibrosis) is dependent on IFN-γ and appears to be controlled by a locus located on 6q23, near the gene encoding IFN-γ receptor β-chain. Mutations that modulate IFN-γ gene transcription are associated with differences in susceptibility to schistosome-induced disease as well. In *Ascaris lumbricoides* infection, intensity of infection has been mapped to loci on chromosomes 1 and 13. Association studies have provided evidence for MHC control of pathology in schistosomiasis and filariasis. Finally, promoter polymorphisms of the IL-10 gene have been demonstrated to affect the immune responses to *Onchocerca volvulus* infection. Because susceptibility and resistance to helminth infections are considered complex traits, the significance of the genetic underpinnings remains to be determined.

T CELLS AND PROTECTIVE IMMUNE RESPONSES

T cells are essential in mediating the expulsion of gastrointestinal nematodes. Mice lacking T cells are defective in their ability to expel *Trichuris muris* but resistance can be reconstituted by transfer of T cells from normal mice. Also, CD4 T cells from infected mice can transfer protective immunity to severe combined immunodeficiency (SCID) mice (lacking both B and T cells), indicating that CD4 T cells but not CD8 T cells are important for protective immunity. Similarly, T cells were shown to be required for expulsion in *Nippostrongylus brasiliensis* infection.¹⁷ Both nude mice and SCID mice are susceptible to infection with Brugian parasites whereas mice that lack either CD4 T cells or CD8 T cell are not.¹⁸ In schistosome-infected mice, T cells are essential in forming host-protective granulomas around the eggs deposited in the liver. Indeed, SCID mice infected with *S. mansoni* die because of the exacerbated egg-induced inflammation related to their inability to form granulomas to sequester the eggs in the tissues.

CYTOKINES AND PROTECTIVE IMMUNE RESPONSES

The role of cytokines in protective immunity has been extensively studied in murine models of both gastrointestinal helminths and tissue-invasive helminths. Effector Th2 cells clearly mediate protective immunity to intestinal nematodes through multiple mechanisms.¹⁷ The cytokines involved in this response are IL-4, IL-5, IL-9, and IL-13. Most of the studies involve four parasitic rodent models of gastrointestinal nematode infections: *Trichinella spiralis*, *Heligmosomoides polygyrus*, *N. brasiliensis* and *Trichuris muris*. These studies show that: (1) CD4 T cells are crucial for host protection; (2) IL-4 is required for host protection and limits host pathology; (3) IL-13 can substitute for IL-4 in some, but not all, infections; (4) IL-2 and IFN-γ inhibit protective immunity; and (5) IL-4 and IL-13 have multiple effects on the immune system and gut physiology, leading to protection. IL-4 and IL-13 can act through a common receptor, IL-4Rα, that signals through Stat6, both of which are required for host protection (either IL-4Rα or Stat6-deficient mice fail to clear infection). Other mediators of protection include mast cells, IL-4R-stimulated intestinal muscle cells, and IL-13-stimulated epithelial goblet cells. IL-4R-dependent effects include increased mucosal epithelial-cell permeability, decreased sodium-dependent glucose absorption, and increased smooth-muscle contractility, all of which create an inhospitable environment

leading to worm expulsion from the intestinal lumen. In addition, release of reactive oxygen intermediates that can damage the worm directly and changes in mucus quality that facilitate worm entrapment also aid in the elimination of the parasite.¹⁹ Finally, IL-13 in conjunction with the chemokine CXCL10 increases the rate of epithelial cell turnover in the large intestine, acting as an epithelial escalator to expel *Trichuris muris*.

While the role of Th2 cytokines in immunity to gastrointestinal helminth infection is well defined, their role in protective immunity to tissue-invasive helminths is not as clear. In murine models of schistosomiasis, protective immune responses can be generated by vaccination with irradiated cercariae. This resistance is dependent upon a Th1-mediated immune response consisting of macrophages and endothelial cells activated by IFN- γ and TNF- α -producing nitric oxide and Th1-associated antibodies, IgG_{2a} and IgG_{2b}. In contrast, studies in rats and epidemiological studies in humans suggest that Th2-mediated effector mechanisms involving IgA and IgE antibodies as well as eosinophils are central to protective immunity. In addition, control of a primary infection in a naïve mouse is dependent on the presence of IL-4 and IL-10, in the absence of which exacerbated pathology results. Protective immunity to filarial infections in mice is dependent primarily on Th2 responses in mice. Thus, mice lacking IL-4, IL-4R, or Stat6 are all susceptible to infection with *Brugia* parasites. Interestingly, IFN- γ also has a protective role, since mice lacking IFN- γ exhibit impairment in the elimination of the parasite. Therefore, protective immunity to tissue-invasive helminths requires coordination of both Th1 and Th2 responses.

Finally, IL-5 appears to play an important role in host protection to helminth infections, possibly due to its role in the differentiation, maturation, and survival of eosinophils. Thus, while IL-5 appears not to be important for protection against *Schistosoma mansoni*, *Trichinella spiralis*, *Toxocara canis* and *Trichuris muris*, it has an essential role in protection against *Onchocerca volvulus*, *O. lienalis*, *Brugia malayi*, *B. pahangi*, *Litomosoides sigmodontis*, *Strongyloides stercoralis*, *S. ratti* and *Angiostrongylus cantonensis*. These nematodes exhibit increased worm burdens, delayed expulsion, or impaired clearance of infection when IL-5 is absent or depleted.¹⁴

ANTIBODIES AND PROTECTIVE RESPONSES

Antibodies also play a major role in mediating protection to some but not all helminth infections. In human studies on schistosome-infected individuals, it is clear that elevated parasite-specific IgE correlates with resistance to reinfection and acquisition of primary resistance. IgE has been implicated in the expulsion of nematodes from the gut and respiratory tract, in part by enhancement of eosinophil cytotoxic responses in an antibody-dependent cell-mediated cytotoxicity mechanism and indeed this has been demonstrated *in vitro* for *Schistosoma mansoni*. In addition, *in vivo* data from mice deficient in IgE showed increased worm burdens with *S. mansoni* and *B. malayi* indicating an important role for IgE in host defense. Again using genetically manipulated mice models, IgM has been shown to be crucial for host protection against *B. malayi* and to *Strongyloides stercoralis*. B1 B cells, a subset of B cells that secrete IgM, appear to be an important component of this protective axis.

EOSINOPHILS AND PROTECTIVE IMMUNITY

The role of eosinophils in mediating protection against helminth infection is not so clear despite the consistent association of eosinophilia with helminth infections. The function of eosinophils has been studied in

animal models using IL-5-deficient or transgenic mice to abolish or increase eosinophil numbers or by depleting eosinophils selectively using an antibody to the eotaxin receptor CCR3. Increase in eosinophil numbers and survival has been seen to correlate with host protection to *Angiostrongylus cantonensis*, *O. volvulus*, *L. sigmodontis*, *Strongyloides stercoralis* and *S. ratti*. On the other hand, depletion of eosinophils did not alter the course of several helminth infections, including *Schistosoma mansoni*, *Mesocostoides corti*, *Trichinella spiralis* and *Trichuris muris*. In addition, both eotaxin and eosinophils have been shown to be important for protection against filarial parasites.^{14, 20} Recently, transgenic mice lacking eosinophils have been generated and experimental infection with *S. mansoni* reveals no effect of eosinophils on infection or disease.

The mechanism of protection mediated by eosinophils is thought to be antibody-dependent cell-mediated cytotoxicity, as observed in *S. mansoni* studies *in vitro* or through release of eosinophil granule contents. Purified eosinophil granule contents have been demonstrated to kill effectively *B. malayi* microfilariae, schistosomula, and *Trichinella spiralis* newborn larvae *in vitro*. While eosinophils are required for elimination of *O. volvulus* and *Brugia pahangi*, eosinophil peroxidase (EPO) and major basic protein (MBP), two eosinophil granule proteins are not required for protection.^{14, 20}

MAST CELLS AND PROTECTIVE IMMUNITY

Gut nematode infection induces a high degree of mucosal mastocytosis and this is dependent on IL-4, IL-5, IL-9, IL-10, and IL-13. The role of mast cells in the expulsion of some gastrointestinal helminths has been demonstrated using mice having a genetic mutation in *c-kit* or *c-kit* ligand. These mice lack mast cells in addition to other defects and are impaired in the elimination of *Strongyloides venezuelensis* and *T. spiralis*. It has been further demonstrated that mast-cell products such as histamine, serotonin, and mast cell protease-1 are involved in this expulsion process. Finally, mast-cell-dependent increase in epithelial permeability and degradation of tight junction proteins, including occluding, occurs during intestinal infection facilitating expulsion of parasites. However, studies involving *N. brasiliensis* or *Trichuris muris* reveal normal expulsion kinetics in the absence of mast cells, indicating that mast cells are not necessary for protection in these infections.¹⁵

KEY CONCEPTS

HELMINTH-INDUCED IMMUNE RESPONSES

- >>> Characterized by immunoglobulin E antibody production, tissue and peripheral blood eosinophilia, mast-cell involvement, and type 2 cytokines
- >>> Implicated in both pathogenesis of helminth infections and in mediating immunologic protection
- >>> Regulated by T cells and other cells producing interleukin-4 (IL-4), IL-5, IL-10, and/or IL-13

Characterized by the induction of regulatory T cells that mediate downmodulation of immune responses to helminth infections and impact bystander phenomena such as allergy and autoimmunity

■ PATHOLOGY ASSOCIATED WITH IMMUNE RESPONSES IN PARASITIC HELMINTH INFECTION ■

Typically, pathological findings associated with each parasitic infection are different and relate to the presence of the parasites in host tissues, but there are pathologic reactions that stem directly from the host immune response.

IMMUNE COMPLEXES

Immune complexes are potent mediators of localized inflammatory processes that form in many parasitic infections, presumably due to the chronic low-dose antigen release seen in these infections. Circulating immune complexes have been identified in both experimental and human filarial and schistosomal infections. These have been shown to induce lymphatic inflammation and vasculitis in a filarial infection as a result of their deposition. In addition, a common manifestation of immune complex-mediated pathology, immune complex glomerulonephritis (ICGN), has been documented by renal biopsy in patients with schistosomiasis and filarial infections. Although the incidence of helminth-induced ICGN is unknown, proteinuria and/or hematuria have been reported in up to 50% of patients with loiasis or lymphatic filariasis, and may be exacerbated by chemotherapy. Also, other manifestations of immune complex-mediated damage, such as reactive arthritis and dermatitis, have been described in patients with helminth infections.

AUTOANTIBODIES

Autoantibodies have been implicated as causing disease in a variety of helminth infections, including filarial infections, schistosomiasis, and hookworm infection, and felt to reflect a polyclonal B-cell expansion that often accompanies these infections. Autoantibodies against nuclear material have been found in a vast majority of patients with chronic schistosomiasis. In addition, antibodies to calreticulin and the neutrophil granule protein defensin are common in individuals with an immunologically hyperresponsive form of onchocerciasis (localized onchodermatitis or sowda), characterized by severe skin pathology. Anti-retinal antibodies in serum and ocular fluids are found in onchocerciasis and have been postulated to play a role in the pathogenesis of retinal degeneration and optic atrophy occurring in the infection.

GRANULOMATOUS REACTIONS

Although granulomatous reactions occur in many helminth infections (e.g., toxocariasis, *Angiostrongylus* infections, and lymphatic filariasis), parasitic granulomas have been best studied in *Schistosoma mansoni* infections, where granulomatous and fibrosing reactions against tissue-trapped eggs are orchestrated by CD4 T cells. The granulomas are composed primarily of eosinophils, lymphocytes, and macrophages and the fibrosis that results from the cellular response is the principal cause of morbidity in infected patients. The severity of the inflammatory process varies markedly both in humans and in experimental animal models, with severe pathology associated with Th1 responses and milder pathology with Th2-dominant responses.²¹

Studies in murine models of granuloma formation have demonstrated the important roles of IL-13 and TNF- α . IL-13 is a key mediator of chronic infection-induced liver pathology. IL-13 signaling is mediated by the type 2 IL-4 receptor, which consists of the IL-4R α and the IL-13R α -1 chains. However, IL-13 can also bind to another receptor composed of IL-13R α -2, which acts to inhibit the actions of IL-13. IL-13R α -2 appears to play an important role in preventing pathology since mice lacking IL-13R α -2 fail to limit granuloma formation in the chronic phase of *S. mansoni* infection. In addition, IL-13R α -2-deficient mice develop severe IL-13-dependent fibrosis and portal hypertension and succumb to infection.²² Finally, TNF- α is necessary for egg-laying and excretion of eggs from the host and, in addition, TNF- α is necessary and sufficient to reconstitute granuloma formation in SCID mice.²³

Lymphatic filariasis is associated with similar fibrotic reactions, wherein adult parasites residing in the afferent lymphatic channels and lymph nodes induce "scarring," felt to be partially responsible for the lymphedema and chyluria found in this condition.²⁴

TOLL-LIKE RECEPTORS

Some pathology in lymphatic filariasis has been associated with the release (or presence) of an endosymbiotic, *Rickettsia*-like bacterial organism of the *Wolbachia* genus. *Wolbachia* are known to stimulate immune cells through TLR2- and TLR4, causing release of proinflammatory cytokines, which has been linked to causing lymphatic pathology.²⁵ In addition, *Wolbachia*-TLR4 interaction has been shown to be a mechanism underlying corneal inflammation seen in onchocerciasis.

IMMEDIATE HYPERSENSITIVITY RESPONSES

Immediate hypersensitivity responses are associated with the early and/or acute phase of infections with invasive helminth parasites, such as *Ascaris*, hookworm, schistosomes, or filariae. Patients do manifest symptoms suggestive of allergic reactivity, such as wheezing or urticaria. Furthermore, in clinical syndromes associated with *Loa loa* infection (with its angioedematous Calabar swellings), with tropical pulmonary eosinophilia, and with larva currens in strongyloidiasis, IgE-mediated reactions are felt to underlie these signs and symptoms. Eosinophil-associated pathology is found even more frequently in response to helminth infection than is IgE-mediated pathology. Evidence has been accumulating in parasitic diseases associated with profound or extreme hypereosinophilia, as in endomyocardial fibrosis associated with loiasis, or in the tropical pulmonary eosinophilia syndrome, that the major cause of tissue destruction appears to be the eosinophil and its toxic granule-associated molecules.¹⁴

■ MECHANISMS OF EVASION AND IMMUNE REGULATION BY HELMINTH PARASITES ■

Helminths exert profound immunoregulatory effects on the host immune system with both parasite antigen-specific and more generalized levels of immune suppression. It has been shown that patients with schistosomiasis or filarial infections have markedly diminished responses to parasite antigens and, in addition, some measurable attenuation in responses to

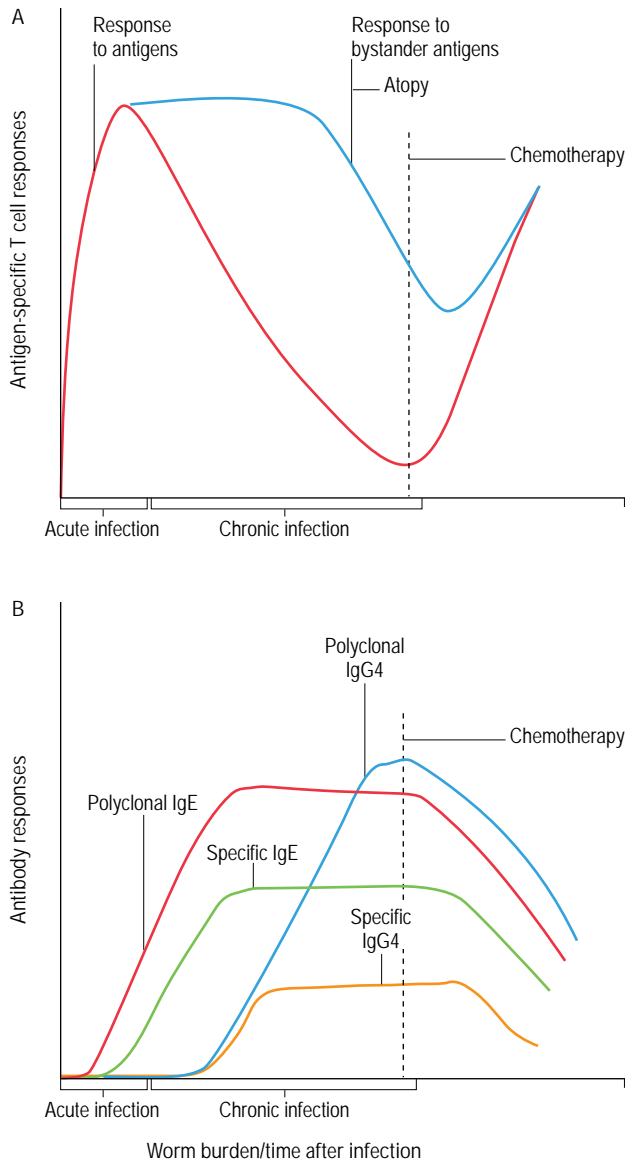

Fig. 29.3 T-cell and antibody responses to helminth infection. Vigorous T-cell response to acute infection is followed by a downregulation due to chronic exposure. This hyporesponsiveness can be partially reversed by chemotherapy or immune modulation. Antibody responses are characterized by an initial polyclonal and antigen-specific immunoglobulin E (IgE) production followed by induction of polyclonal and antigen-specific IgG₄. The upper panel is modified from reference 12.

bystander antigens and routine vaccinations (Fig. 29.3). Thus, while host immunosuppression is usually antigen-specific, chronic infection can be associated with some spillover effects.⁵ The long lifespan of helminth parasites is major evidence of successful immune evasion strategies of these parasites. Among the mechanisms utilized by parasites to avoid immune-mediated elimination are those of evasion – the use of

sequestration, camouflage, and antigenic variation – and suppression, regulation, or blockade of immune effector pathways.

MECHANISMS OF EVASION

Sequestration

Pathogens become sequestered when they enter into intra- or extracellular compartments, such as the central nervous system, that are not accessible to all components of the immune response. Encystation, as occurs in infections with the metacestodes *Echinococcus* spp. and *Taenia solium* or *Trichinella spiralis*, is considered a mechanism of protection against immune attack. It has been demonstrated, however, that parasite antigens and host antibodies can traverse the cyst membranes, indicating that the cyst environment is not completely immunologically inert. Similarly, in *O. volvulus* infection, the parasites are surrounded by a relatively avascular, acellular fibrotic capsule that serves as a barrier to the host response. Tropism for immunologically relatively protected environments (e.g., the eye in *O. volvulus* infection and the intestinal lumen for intestinal nematodes) contributes to sequester the parasite from the host effector systems.

Camouflage

Schistosomes adsorb host molecules on to their tegument, including MHC antigens, the Fc portion of immunoglobulin, and blood group antigens. They probably serve to disguise the parasite from host immune attack. A related form of camouflage occurs when the parasite synthesizes proteins that share epitopes with host tissues; such molecular mimicry can exploit host immune tolerance against self-determinants.²⁶

Shedding of surface antigen and bound antibodies

Parasites that shed antigen upon recognition by host antibody may also enhance their survival. This phenomenon has been described for *Schistosoma mansoni* parasites.²⁶ Tissue- and intestinal-dwelling nematodes also periodically release portions of their outer glycocalyx coat and finally discarded or secreted antigens might conceivably serve as soluble decoys to divert the immune system.²⁷

Parasite-derived factors

B. malayi secretes a cysteine protease inhibitor, cystatin, which interferes with both the cathepsins and asparagine endopeptidase involved in the processing of peptides for the MHC class II pathway. Similar inhibitors have been described for *O. volvulus* and *N. brasiliensis*. In addition, cystatins from helminth parasites can modulate T-cell proliferation and elicit upregulation of IL-10 expression.²⁸ Other modulators, such as prostaglandins and other arachidonic acid family members, such as prostaglandins E₂ and D₂ are known to inhibit IL-12 production by DC. Aspartic proteases from *Ascaris lumbricoides* have been shown to block efficient antigen processing dependent on proteolytic lysosomal enzymes.²⁹

Parasite-derived factors have been isolated that interfere with T-cell function. For example, the secretion of immuno-dominant molecules such as hapten phosphorylcholine may act as an inhibitor of T-cell reactivity. A phosphorylcholine-bearing filarial secreted product ES62 renders macrophages refractory to IFN- γ /lipopolysaccharide stimulation of IL-12 production and induces differentiation of DC to a Th2-inducing phenotype,

both skewing against induction of Th1 responses. Other molecules with similar function include lacto-*N*-fucopentantose III and lacto-*N*-neotetraose from *S. mansoni* and *Acanthocheiloneuma viteae* ES antigen Av17 that can inhibit T-cell proliferation by inducing IL-10 production and suppressive macrophage phenotype.³⁰ The abundant larval transcript genes (*ALT*), which account for 5% of the cDNA expressed by the infective stage larvae of *B. malayi*, are thought to be expressed by the mosquito-stage parasite to mediate compromise of cell-mediated immunity in the host.³¹ Finally, lipid fractions from *S. mansoni* adult worms and eggs interact with TLR2 on DC resulting in a Th2 skewing of the immune response but also induction of IL-10-producing regulatory T cells.

Helminth parasites also utilize mechanisms involving cytokine mimicry and interference to establish chronic infection. Thus parasites produce cytokine and chemokine-like molecules to interfere with the function of host innate immune products. The first helminth cytokines were found to be homologues of TGF- β expressed by *B. malayi* and both schistosomes and filarial parasites express members of the TGF- β receptor family. Similarly, *Echinococcus granulosus* expresses a TGF- β ligand, and thus all helminth groups might have the potential to exploit TGF- β -mediated immune suppression.¹³ Various helminths, including *B. malayi* produce homologues of macrophage migration inhibitory factors (MIF), which are known to activate an anti-inflammatory pathway through SOCS-1, a molecule involved in cytokine signaling.¹³ *Trichuris muris* is known to express a homologue of IFN- γ , which binds to the IFN- γ receptor *in vitro* and induces signaling. As *T. muris* is expelled by IL-4, secretion of an IFN- γ -like protein can prolong its survival.²⁹

Similarly, helminth parasites utilize chemokine or chemokine receptor-like proteins to evade protective immunity. *Ascaris suum* is known to express a neutrophil chemoattractant with chemokine-binding properties. *Schistosoma mansoni* eggs secrete a protein, smCKBP (*S. mansoni* chemokine-binding protein), that binds the chemokines CXCL8 and CCL3 and inhibits their interaction with host chemokine receptors and their biological activity, resulting in suppression of inflammation. Cells of the innate immune system utilize C-type lectin receptors such as DC-SIGN, L-SIGN, the mannose receptor, macrophage galactose-binding lectin, and other lectins to recognize particular glycan antigens from helminth parasites. Interestingly, *S. mansoni* and *Toxocara canis* express their own glycan and lectin antigens that act as molecular mimics of host antigens, thereby interrupting or misdirecting host inflammatory responses.¹³

Other parasite products mediate their effect by blocking effector functions, including recruitment and activation of inflammatory cells, and limiting the destructive potential of activated granulocytes or macrophages in the local extracellular milieu. For example, the host chemoattractant platelet-activating factor (PAF) is inactivated by a complementary enzyme PAF hydrolase secreted by *Nippostrongylus brasiliensis*.²⁹ Eotaxin-1, a potent eosinophil chemoattractant, is degraded by metalloproteases from hookworms. *Ancylostoma caninum* secretes a protein called neutrophil-inhibitory factor that binds the integrins CD11b/CD18 and blocks adhesion of activated neutrophils to vascular endothelial cells and also the release of H₂O₂ from activated neutrophils. *Necator americanus* ES products also bind to host NK cells and augment the secretion of IFN- γ , which might cross-regulate deleterious Th2 responses.³² IPSE/alpha-1, a major immunogenic component secreted by schistosome eggs, can directly induce IL-4 production from basophils and thereby influence CD4 T-cell differentiation.

The proteases encoded by the host, such as neutrophil elastase and cathepsin G, are inhibited by proteases called serpins, which are released

by a variety of helminth parasites and the activation of complement is inhibited in *Echinococcus granulosus* infection by the uptake of host-inhibitory factor H on to the hydatid cyst wall. Finally, helminths susceptible to oxidant-mediated killing express both secreted and membrane-associated enzymes, such as superoxide dismutase, glutathione-S-transferase, and glutathione peroxidase, molecules thought to play a significant role in assisting parasite survival in inflamed tissues.

HOST-RELATED FACTORS

Regulatory T cells

Natural regulatory T cells play an important role in the downmodulation of immune responses in infectious diseases, tumor immunology, and autoimmunity (Chapter 16). They are characterized by the expression of surface markers, CD25, and to a lesser extent GITR and by the transcription factor Foxp3. Natural regulatory T cells can turn off effector T-cell responses mostly by a direct contact-mediated mechanism but can also act via suppressive cytokines. Adaptive regulatory T cells, that also express CD25, act through the induction of cytokines, particularly IL-10 and TGF- β . Evidence for the involvement of regulatory T cells in helminth-mediated downmodulation of the immune response has been accumulating in recent years. IL-10 and TGF- β , both factors associated with regulatory T cells, are elicited in response to helminth infections, and *in vitro* neutralization of IL-10 and TGF partially restores T-cell proliferation and cytokine production in lymphatic filariasis.³³ Similar reversals of immunosuppression are observed in onchocerciasis and schistosomiasis, with IL-10-producing natural regulatory T cells from egg-induced granulomas being important for host survival. In addition, T-cell clones secreting IL-10 and TGF- β have been isolated in onchocerciasis.³⁴ Recently, treatment of mice infected with *Litomosoides sigmodontis* with anti-CD25 and anti-GITR antibodies has been shown to render mice resistant to infection, implicating regulatory T cells in the susceptibility to this filarial infection.³⁵ Finally, in human lymphatic filariasis and in mouse models, increased expression of Foxp3 has been shown to be associated with diminished responses in filarial infections.^{11,36}

Hyporesponsive T cells

Effector T-cell responses can be turned off or modulated through a variety of mechanisms, including CTLA-4 and PD-1. Interestingly, increased expression of CTLA-4 and PD-1 has been demonstrated in filarial infections, and blocking of CTLA-4 can partially restore a degree of immunological responsiveness in cells from infected individuals.^{11,37} Moreover, T cells have decreased induction of the T-bet, the Th1 master regulatory gene indicating a failure at the transcriptional level to differentiate into Th1 cells. Finally, T cells from filarial infected individuals exhibit classical signs of anergy, including diminished T-cell proliferation to parasite antigens, lack of IL-2 production, and increased expression of E3 ubiquitin ligases.¹¹

Modulation of antigen-presenting cell function

DC are usually the first antigen-presenting cells to encounter parasites, and helminth modulation of DC function has been characterized. Filarial parasites induce downregulation of MHC class I and class II as well as cytokines and other genes involved in antigen presentation, thereby

rendering DC suboptimal in the activation of CD4 T cells.⁸ Schistosomes induce similar effects on DC with subsequent Th2 polarization and inhibited responses to Th1-inducing TLR ligands.³⁸ Experimental helminth infection with *B. malayi*, *N. brasiliensis* and *Toxocara canis* has been shown to elicit macrophages with an alternative activation phenotype, leading to marked suppression of target cell proliferation and induction of Th2 responses.¹³ A phosphoryl-choline-containing filarial nematode-secreted glycoprotein ES-62 has also been shown to polarize DC and macrophages toward an anti-inflammatory phenotype.

Apoptosis

Another mechanism of immune evasion is the ability of some helminths to induce host cell apoptosis. In schistosomes, a molecule termed “schistosome apoptosis factor” has been identified that induces apoptosis of CD4 T cells through a Fas-FasL-dependent mechanism. Apoptosis of CD4 T cells has also been demonstrated *in vivo* in the spleens of *Brugia*-infected mice. Finally, *Brugia* microfilariae can interact with DC and induce their apoptosis through a caspase-dependent mechanism.

REGULATION OF ALLERGY AND AUTOIMMUNITY IN HELMINTH INFECTION

The hygiene hypothesis postulates that the stimulation of the immune system by microbes or microbial products protects from the development of inflammatory and atopic disorders.³⁹ Human studies have demonstrated that people living in areas endemic for helminth infections have a decreased reactivity to skin tests for allergens and may have less asthma.⁴⁰ Experimental animal models also reveal the protective effect of helminth infections against atopy and asthma.⁴⁰ Several mechanisms have been proposed for the helminth-induced protection from allergy, chief among them being the induction of regulatory T-cell activity and immunosuppressive cytokines, including IL-10 and TGF- β .⁴⁰ Similarly, exposure to helminth parasites has been shown to prevent the onset of Th1-mediated diseases such as multiple sclerosis, diabetes mellitus, and Crohn's disease in experimental animal models.⁴¹ Finally, helminth infection may prove useful as a therapeutic tool for autoimmune disease, as evidenced by the promising preliminary data relating to the ingestion of *Trichuris suis* eggs and the improvement of disease symptoms in individuals suffering from inflammatory bowel disease.^{42, 43}

VACCINES AGAINST HELMINTH PARASITES

Vaccines against helminth infections are likely to be a necessary tool for their elimination and eradication for several different reasons. First, reinfection after chemotherapy is common and occurs rapidly in a majority of intestinal helminths and in some of the tissue-invasive ones as well. Hence, with sustained, continued community-based treatment, high rates of community transmission occur. In addition, there is evidence for the emergence of drug resistance, albeit rare. Second, control of the vectors involved in transmission (e.g., mosquitoes in lymphatic filarial parasites) or intermediate hosts (e.g., snails in schistosomiasis)

has been difficult to achieve for both logistical and economic reasons; the emergence of pesticide resistance is also problematic. Third, although much of the geohelminth burden at least could be reduced by improvements in sanitation, water management, and housing, for the areas most endemic for helminth parasites, this has not been achieved. Thus, vaccination may ultimately provide the most efficacious way both to prevent parasitic disease and to interrupt transmission.

Over the last several years, a considerable amount of effort has gone into developing vaccines against helminth parasites, with limited success. There are obviously several impediments to the development of helminth vaccines, the most important being the lack of good animal models for many of these infections. In addition, the complexity of the parasite lifecycles, their ability to evade the host immune system, difficulty in understanding the mechanism of host resistance, and an inability to define methods for rational screening of potential vaccine targets have limited progress towards vaccine development.⁴⁴ The development of successful recombinant vaccines against cestode parasites is in stark contrast to the somewhat modest success achieved against other helminth parasites. Recombinant oncosphere antigens have been used in the development of effective vaccines in the intermediate hosts of *Taenia ovis*, *Taenia solium*, *T. saginata* and *Echinococcus granulosus*.⁴⁵

RADIATION ATTENUATION

Immunity to a variety of helminth infections can be achieved by using radiation-attenuated live larval stages of the parasite. Radiation attenuation optimally allows for short-term viability, active metabolism, and some tissue migration in the face of arrested development. Irradiated larval vaccines were developed for commercial use against veterinary nematodes and for a number of other helminth parasites. Although larval attenuation by radiation is an effective method for the production of vaccines, the inability to obtain large enough numbers of such larvae makes such an approach not feasible.

STRATEGIES TO IDENTIFY HELMINTH ANTIGENS AS POSSIBLE VACCINE CANDIDATES

“Rational screening” for antigens is a concept which presumes that certain antigens have some intuitive appeal as targets for immune attack and, as such, they are identified and studied.⁴⁶ The lessons learned from the use of irradiated larval vaccines have been helpful in designing effective recombinant vaccines. Thus, the requirement for larval viability suggests that excretory/secretory antigens can be attractive vaccine candidates. Many of these excretory/secretory antigens are enzymes and include metalloproteases, hyaluronidases, acetylcholinesterases, and proteases but also others like activation-associated secreted proteins. Other candidates include molecules important for parasite invasion, growth, and development (e.g., molting related proteins), metabolism (e.g., transporters or enzymes necessary for parasite survival), or protection against immune attack (e.g., antioxidants).⁴⁷

Previously, immunologically based screening methods using vaccinated or immune animals, monoclonal antibodies raised against parasite antigens, or sera from “immune” human populations were used extensively. These antibodies were then used to identify antigens, either directly by isolating the parasite protein or indirectly by screening recombinant expression libraries. With the advent of parasite genome and expressed sequence tags (EST) projects, identification of entire gene families by database mining has

CLINICAL RELEVANCE

APPROACHES TO HELMINTH VACCINE DEVELOPMENT

- >> Radiation-attenuated larval parasites have been efficacious in veterinary practice, but not feasible for wide-scale application
- >> Few helminth vaccine candidates are in human clinical trials
- >> Recent emphasis has been on DNA vaccines, subunit vaccines, "rational" vaccine design, parasite genome analysis, and the development of novel vectors

expedited the search for rational vaccine targets. Advances in proteomics and high-throughput biochemical analysis have improved and facilitated the methods to determine the structure and function of the proteins encoded by this genetic information.⁴⁶

DNA AND RECOMBINANT PROTEIN VACCINES

DNA vaccines are made of DNA coding sequences that specify the candidate antigen protein inserted into a bacterial plasmid under the regulation of a eukaryotic promoter. DNA vaccines can be administered by multiple routes and can induce virtually all types of immune response: CD8 T-cell cytotoxicity, CD4 T-cell help and antibodies. In addition, DNA vaccines contain unmethylated DNA motifs that can stimulate the innate immune response through TLR9 and act as a self-adjuvant. DNA and protein vaccines can be administered as a prime-boost regimen with DNA used for priming and protein vaccines used for boosting. DNA and protein vaccines have been used in experimental models of schistosomiasis, filariasis, *Strongyloides* and hookworm infection. These include the candidate antigens irV5, paramyosin, Sm14, glutathione-S-transferase, triose phosphate isomerase and Sm23 for schistosomiasis, paramyosin, heart shock proteins, ALT-1 and ALT-2 for filariasis, chitinase and ALT-1 for onchocerciasis, Asp-1, Asp-2, metalloprotease-1 for hookworm infection and SS-eat-6 for *Strongyloides* infection.⁴⁸

HUMAN CLINICAL TRIALS

Very few helminth vaccine candidates have reached human clinical trials. One is the 28-kDa glutathione-S-transferase protein from *Schistosoma mansoni*. This vaccine (in alum) has been shown to elicit antibody responses characteristic of Th2 immunity in human trials. This vaccine is primarily aimed at reducing morbidity by affecting female worm fecundity and to improve the efficacy of chemotherapy.⁴⁹ Similarly, ASP-2 a secreted protein from *N. americanus* has been selected for evaluation as a recombinant vaccine candidate based on human epidemiological and experimental animal model studies. The vaccine is currently undergoing phase II studies.⁵⁰

With rapid advances in the parasite genomics and proteomics as well as the newer, better vaccine delivery systems offering better and more rapid assessment development, prospects for newer anti-helminth vaccines are excellent, although the potential lack of commercial markets imposes a significant impediment to their development.

Evaluation of the immunodeficient patient

Mary E. Paul, William T. Shearer

30

ETIOLOGY

Immunodeficiency diseases can present with symptoms of susceptibility to infection but may also involve allergy, autoimmune disease or lymphoproliferation. There are over 120 primary immunodeficiency diseases (PIDs) and they can affect any aspect of the immune response. PIDs are generally hereditary and congenital deficiencies of the immune system. In contrast, secondary immunodeficiencies, discussed in detail in Chapter 38, can present at any time, in that they are acquired disruptions in immune function that increase susceptibility to infection. Examples include severe combined immune deficiencies, DiGeorge syndrome, and chronic granulomatous disease, which are usually diagnosed in infants and young children. However, common variable immunodeficiency (CVID), an immunodeficiency of impaired antibody production that has an incidence between 1:10 000 and 1:50 000, typically does not cause symptoms until the third decade of life.¹ This chapter introduces the PIDs and presents an approach to the evaluation of the immunodeficient patient.

FREQUENCY AND DIFFERENTIAL DIAGNOSIS

Nonimmune causes for recurrent infections have to be considered in the differential diagnosis of the immunodeficiency disorders. These include disorders that disrupt the usual clearance mechanisms, such as posterior

urethral valves or urethral stenosis in a patient with recurrent urinary tract infection; cystic fibrosis in individuals who have recurrent sinusitis or pneumonia; and allergic rhinitis in patients who have recurrent sinusitis or otitis media. Disruption of barrier protection can lead to infection, for example in patients with skin disruption due to eczema or burns, or individuals with cerebrospinal fluid leaks following bony injury to the cranium. Patients with low antibody levels may be able to produce antibody normally, and instead have loss of antibody due to a protein-losing enteropathy, nephropathy, or massive protein loss through the skin, such as is found in severe eczema or burns. Secondary immunodeficiency can result from, for example, malnutrition, diabetes mellitus, and sickle cell anemia.

The incidence of congenital immunodeficiencies varies from the common selective IgA deficiency (1:300–1:700) to the rare X-linked severe combined immunodeficiency (1:50 000–1:100 000).² Chronic granulomatous disease (CGD) occurs with an incidence of 1:200 000.³

The hallmark of immunodeficiency is recurrent serious infection with frequent treatment failures. These disorders present in a male:female ratio of 5:1 in children and infants and 1:1.4 in adults. More than 120 primary immunodeficiency disorders were recognized at the Budapest 2005 meeting of a committee of experts convened under the aegis of the International Union of Immunological Societies.⁴ Examples and the typical presentation for various primary immunodeficiency disorders are listed in Table 30.1.

KEY CONCEPTS

FEATURES OF CONGENITAL ANTIBODY DEFICIENCY

- >> Free of infections until 7–9 months of age, when antibodies that passed through the placenta from mother to infant are below protective levels.
- >> Severe infections with bacterial organisms, especially with encapsulated bacteria such as *Streptococcus pneumoniae*.
- >> Growth failure is generally not seen, except in the patient who has been chronically ill with severe infection.

ETIOLOGY

Although the etiology of many immunodeficiencies has not been elucidated, defective genes and gene products have been identified in certain PIDs. Examples of secondary immunodeficiencies include those conditions that occur as a consequence of the exposure of the patient to immunosuppressive agents, infectious diseases, infiltrative diseases, and metabolic diseases as discussed throughout this book. Disruptions in the function of the immune system can occur due to problems in development, in cell-to-cell communication, and in cell function or structure. Examples of abnormalities in the immune system that result in disease are listed below. Each of these disorders is discussed fully in subsequent chapters.

Table 30.1 Primary immunodeficiency disorders: examples and typical presentation

Disorder group	Examples of specific disorders	Typical presentation
T-cell and combined immunodeficiency	<p>X-linked SCID (γ-chain deficiency) CD8 Lymphocytopenia (ZAP-70 deficiency) SCID-T⁻ B⁺ NK⁺ JAK3 deficiency Adenosine deaminase deficiency Purine nucleoside phosphorylase deficiency Wiskott-Aldrich syndrome</p> <p>Ataxia telangiectasia</p> <p>DiGeorge anomaly</p> <p>Hyper-IgM syndrome</p>	<p>Failure to thrive, opportunistic infection, rash</p> <p>Thrombocytopenia with bleeding and bruising, eczema, recurrent infection with encapsulated organisms</p> <p>Chronic sinopulmonary disease, cerebellar ataxia, malignancy, oculocutaneous telangiectasia</p> <p>Hypocalcemic seizures due to hypoparathyroidism, cardiac disease, abnormal facies, opportunistic infection</p> <p>Opportunistic infections, recurrent serious pyogenic infections, cytopenias, biliary tract and liver disease</p>
Complement disorder	Terminal component deficiency	Neisserial infection
B-cell or antibody deficiencies	<p>X-linked agammaglobulinemia IgA deficiency Common variable immunodeficiency IgG subclass deficiencies</p>	Recurrent sinopulmonary infections
Neutrophil disorders	<p>Chronic granulomatous disease</p> <p>Leukocyte adhesion deficiency 1</p> <p>Interleukin (IL)-12 deficiency IL-12 receptor (R) deficiency Interferon-γ R deficiency</p>	<p>Deep-seated infection, abscess especially with catalase-positive organisms</p> <p>Recurrent serious bacterial infections, especially on mucosal surfaces or wound sites; poor wound healing, lack of pus</p> <p>Susceptibility to <i>Mycobacteria</i> and <i>Salmonella</i></p>
Disorders of innate immunity	<p>IL-1 receptor-associated kinase 4 (IRAK) deficiency</p> <p>Anhidrotic ectodermal dysplasia with immunodeficiency (EDA-ID or NEMO defect)</p>	<p>Bacterial (pyogenic) infections</p> <p>Anhidrotic ectodermal dysplasia with specific antibody production deficiency and various infections (mycobacterial and pyogenic)</p>
Diseases of immune dysregulation	<p>X-linked lymphoproliferative syndrome lymphoma</p> <p>Autoimmune lymphoproliferative syndrome (ALPS)</p> <p>Immune dysregulation, polyendocrinopathy, enteropathy X-linked (IPEX)</p>	<p>EBV-infection triggered hepatitis, aplastic anemia</p> <p>Defective lymphocyte apoptosis, splenomegaly, adenopathy, autoimmune cytopenias</p> <p>Autoimmune diarrhea, diabetes, thyroiditis, hemolytic anemia, thrombocytopenia, eczema</p>

KEY CONCEPTS

FEATURES OF CONGENITAL CELLULAR IMMUNODEFICIENCY

- >> Onset of thrush, diarrhea and failure to thrive in the first months of life.
- >> Recurrent infections with opportunistic organisms such as *Pneumocystis jiroveci*, *Candida albicans*, varicella, adenovirus, cytomegalovirus, Epstein–Barr virus (EBV), parainfluenza 3.
- >> Lymphopenia.

Disruption of normal immune system development results in immunodeficiency. The absence of Bruton's tyrosine kinase results in arrest of B-cell development at the pre-B-cell stage in congenital X-linked agammaglobulinemia.⁵ Also, T-cell development is abnormal in the X-linked form of severe combined immunodeficiency (SCID) due to abnormalities in the common γ chain of the receptor for interleukins (IL)–2, –4, –7, –9, –15, and –21.⁶ JAK3 deficiency is an autosomal recessive form of SCID with a phenotype similar to that of X-linked SCID. Cytokine signal transduction is abnormal in JAK3-deficient individuals, resulting in abnormal development and function of T cells.² In CD8 lymphocytopenia (ZAP-70 deficiency) abnormal function is a consequence of the absence of a T-cell kinase involved in thymic T-cell maturation and in T-cell receptor-associated signal transduction.²

Immunodeficiency also results when lymphocytes do not communicate properly or process signals correctly. The communication between B and T cells is disturbed in X-linked hyper-IgM syndrome owing to decreased expression of CD40 ligand (CD154) on T cells.⁵ X-linked lymphoproliferative (XLP) syndrome results from unregulated stimulation of B cells by the Epstein–Barr virus. For some XLP patients the absence of a T cell-specific activation inhibitor protein, SAP (signalling lymphocyte-activation molecule-associated protein), leads to this inability to control B-cell proliferation.⁷ Between 10% and 20% of CVID patients have mutations in the gene for a tumor necrosis factor (TNF) receptor family member, transmembrane activator and calcium-modulator and cyclophilin ligand interactor (TACI).⁸ TACI mediates isotype switching in B cells, and B cells from CVID patients with *TACI* mutations did not produce IgG and IgA in response to the TACI ligand, a proliferation-inducing ligand (APRIL).⁸ Also, TACI normally delivers apoptotic signals to B cells, suggesting that abnormal TACI signaling in CVID patients might explain the findings of autoantibodies, lymphoproliferation with splenomegaly and adenopathy, and increased susceptibility to malignant lymphoma and nonlymphoid malignancies.⁸

Abnormal embryonic differentiation of early lymphoid organs may lead to immunodeficiency, as in the case of DiGeorge syndrome. In the full DiGeorge syndrome, an association of cardiac abnormalities, facial malformations, and absent thymus and parathyroids occurs as a result of failure of the third and fourth pharyngeal pouches to differentiate into thymus and parathyroids. There is an associated failure(s) in the development of the primitive heart and/or arteries.

Enzyme defects have also been identified that result in immune deficiency. Adenosine deaminase (ADA) deficiency, for example, has

been found in 17% of cases of SCID (Chapter 35). The absence of this enzyme results in the accumulation of adenosine, deoxyadenosine, and 2'-O-methyladenosine, which results in lymphocyte apoptosis and profound lymphopenia.² A deficiency in purine nucleoside phosphorylase (PNP) is associated with some cases of cellular immunodeficiency with immunoglobulins or Nezelof syndrome.² NADPH-oxidase deficiency causes deficient microbial killing in chronic granulomatous disease.⁹

Immunodeficiency syndromes with autoimmunity can be associated when lymphocytes are not properly regulated. For example, autoimmune lymphoproliferative syndrome (ALPS) occurs as the result of defective lymphocyte apoptosis and manifests with splenomegaly, adenopathy, and autoimmune blood cytopenias.⁴ Immune dysregulation, polyendocrinopathy, enteropathy (X-linked) (IPEX), which manifests with autoimmune diarrhea, diabetes, thyroiditis, hemolytic anemia, thrombocytopenia, and eczema, occurs as a result of the lack of CD4⁺ CD25⁺ regulatory T cells. The defective *FOXP3* gene encodes a T-cell transcription factor.¹⁰

In leukocyte adhesion deficiency type I (LAD I) phagocytes cannot move to areas of infection or injury owing to the absence or poor upregulation of cell surface adhesion molecules. LAD I is due to a deficiency in the cell surface expression of CD18, a 95 kDa molecular weight common β -chain structure.¹¹ CD18 normally forms three distinct surface glycoproteins by binding (co-expression) with three distinct α -chain types; two of these glycoproteins, lymphocyte function-associated antigen-1 (LFA-1) and complement receptor type 3 (CR3), are known to be important in adhesion. Besides chemotaxis, absence of these adhesion molecules on neutrophils is believed to prevent aggregation, phagocytosis, and cytotoxicity.

Other immune deficiencies associated with defective protein synthesis include complement defects in which there is absence of a specific complement component, such as with C2, C3 or C4 deficiency; selective IgA deficiency in which immunity at mucosal surfaces is defective owing to a lack of secretory IgA; and absence of the IgG₂ subclass. In complement protein C2 deficiency type I, no translation of this complement protein is observed. A 28 base-pair (bp) deletion has been found in patients with the C2 null allele and results in a premature termination codon.¹² Other defects that can result in a poorly functioning immune system include metabolic deficiencies and nutrient deficiencies. Protein–energy malnutrition is associated with significant impairment of cell-mediated immunity, phagocyte function and cytokine production.¹³ Undernourished children may have poorly functioning immune systems owing to the lack of micronutrients for proper immune functioning. Vitamin A supplementation given to preschool children decreases morbidity from some forms of diarrhea, HIV, and malaria.¹⁴ Acrodermatitis enteropathica, which has been found in cases of SCID, has been associated with zinc deficiency.¹⁵

Defects in innate immunity have been described that present with bacterial infections. IL-1 receptor-associated kinase (IRAK)-4 deficiency, a deficiency in a protein kinase that is important in mediating signals for innate immune responses, leaves patients vulnerable to bacterial septicemia that presents with mild signs of inflammation.¹⁶ Patients with dysfunction in the nuclear factor (NF)- κ B signaling pathway due to a mutation in the *NF- κ B essential modulator* (*NEMO*) gene present with anhidrotic ectodermal dysplasia and manifestations such as dry skin, conical teeth, and sparse hair, and are at risk for mycobacterial and pyogenic bacterial infection.¹⁶

■ INHERITANCE PATTERNS AND GENETIC DIAGNOSIS ■

Many of the primary immunodeficiency disorders have X-linked inheritance patterns. Single recessive genes result in autosomal recessive inheritance in some forms of immunodeficiency disorders, such as some forms of SCID, CGD, and hyper-IgM syndrome. Familial cases of selective IgA deficiency and common variable immunodeficiency have occurred, and a susceptibility trait can sometimes be traced back for many generations.

For a rapidly growing number of immune deficiency disorders, an abnormal gene has been located and/or the specific gene product and its function are known. In instances where a disorder known to result from a single gene defect is suspected, the diagnosis can be confirmed by molecular genetic analysis (Chapter 101). Standard protocols using Southern, Northern and Western blot analyses, polymerase chain reactions and DNA sequence analysis identify affected patients, affected fetuses prenatally, and carriers.

■ EVALUATION OF THE PATIENT ■

Immunologists are often approached by concerned parents of children with recurrent infections, or by adults who believe that their immune systems are abnormal or have been damaged. The immunologist must take on a role of counselor and advisor of patients with normal immunity who fear immunodeficiency. Explanation of an algorithm such as that in Figure 30.1 is frequently helpful to patients who have a normal immune system. With careful evaluation of the history and physical examination, and with very limited laboratory evaluation, the clinician can often assure patients (or parents) that their (or their child's) immune system is normal.

■ ENVIRONMENTAL HISTORY ■

Environmental conditions may predispose to infection. Infants frequently exposed to infection, such as in the setting of a daycare facility, have more infections than those who are not so exposed. Passive cigarette smoke inhalation also predisposes to illness, including otitis media, pneumonia, and bronchitis. Hygiene of the patient and of caretakers and family members has an impact on the frequency of such infections as impetigo and furunculosis. For patients with allergies, exposure to indoor allergens such as dust mites and molds often worsens congestion and predisposes to sinusitis and otitis media.

■ MEDICAL HISTORY ■

The differential diagnosis of immunodeficiency varies with the time of onset of symptoms. An infant who presents with frequent infections developing from birth to 3 months of age is likely to have maternal immunoglobulin present unless they were born prematurely. Therefore, deficiencies in the immune system at this age are probably due to severe deficiencies in other immune components, such as neutrophils, complement components, or T cells. Apart from frequent infection, other important aspects of the history implicating neutrophil defects include delayed cord separation (beyond 2 weeks) and poor wound healing. DiGeorge syndrome patients usually present very early with hypocalcemic seizures associated with hypoparathyroidism, or with cardiac difficulties rather than with recurrent infections. The presence of protective maternal immunoglobulin means that infants with primary immunoglobulin defects such as X-linked agammaglobulinemia usually do not present until 3–18 months of age, when these antibodies are lost. Infants with Wiskott–Aldrich syndrome – immunodeficiency with thrombocytopenia

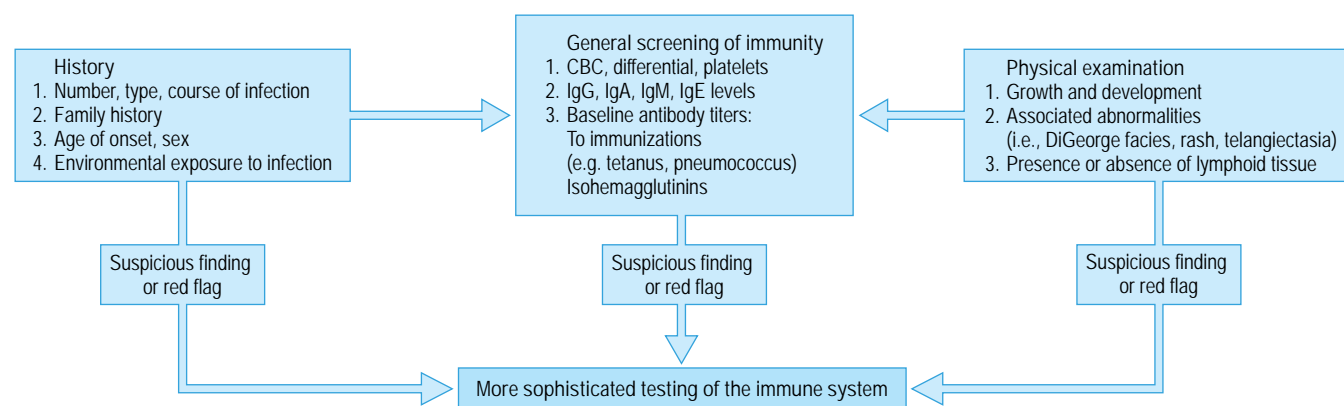

Fig. 30.1 Evaluation of immunity in a patient with recurrent infections involves a careful history and physical examination. Red flags in the history include the following: more than eight upper respiratory tract infections per year for a child; more than four upper respiratory tract infections per year for an adult; more than one episode of pneumonia in the past; one or more life-threatening infections; infections with unusual organisms; unusual course of illness; a family history of early infant deaths or immunodeficiency. The number of upper respiratory tract infections will depend upon exposure. The members of a family with a child in daycare would be expected to have more upper respiratory infections than members of a family with children kept at home. The outlined laboratory tests provide an adequate screen of immunity in a patient with no suspicious findings or red flags in the history or on physical examination.

and eczema – also usually present prior to 18 months of age. In contrast, patients with selective IgA deficiency and common variable immunodeficiency generally do not present until after 18 months.

The immunization history is important. A history of reaction to a live viral vaccine is suspicious for immune deficiency, as infants with T-cell defects, B-cell defects and combined T- and B-cell defects may contract fatal or severe infections from live vaccines.

Historical information regarding the type and severity of illness and infection provides important clues to suggest immune deficiency. Individuals with immunodeficiency may have infections with an unusually prolonged course, unusual severity, or that present as unexpected complications (Fig. 30.2). Recurrent infections that involve more than one site are more suspicious for immune deficiency than those involving a single site. A history of severe infections such as recurrent pneumonia, meningitis, sepsis, septic arthritis, osteomyelitis, or abscess would suggest possible immune deficiency, as does infection with organisms of low pathogenicity, such as *Candida albicans* or *Pneumocystis jiroveci*. Patients with antibody deficiency disorders tend to acquire infections with extracellular pyogenic organisms such as *Haemophilus*, *Pneumococcus*, and *Streptococcus*. In contrast, patients with defects in cell-mediated immunity are more likely to have recurrent infections with viruses, fungi, protozoa, and mycobacteria. Furthermore, infections with unusual bacteria such as *Serratia marcescens*, *Staphylococcus epidermidis*, and *Pseudomonas* may indicate a possible neutrophil defect. Disseminated neisserial infections may be found in individuals deficient in the terminal complement components.

Obtaining a history of atopic disease is helpful. Allergic rhinitis predisposes to sinusitis and otitis media. For some patients, once the allergic rhinitis is well managed the frequency of upper respiratory tract infection diminishes. Also, it is important to elicit a history of recurrent wheezing. At times, an initial history of recurrent pneumonia is actually associated with radiological findings of perihilar cuffing and atelectasis secondary to reactive airways disease or asthma.

Fig. 30.2 CT scan in an infant with CGD. Multiple nodular opacities are seen throughout both lung fields due to fungal pneumonia in an infant with CGD. (From Seeborg et al. A five-week-old HIV-1-exposed girl with failure to thrive and diffuse nodular pulmonary infiltrates. *J Allergy Clin Immunol* 2004; 113: 629, with permission from Elsevier.²⁸)

Family history is vital in evaluation of suspected immunodeficiency. A history of early infant deaths should be sought. A clear pattern of inheritance may be found; information regarding possible consanguinity should be obtained. Family members of immunodeficient patients will often have a history of autoimmune disease or of connective tissue disease.

PHYSICAL EXAMINATION

The physical examination supplies important clues about the etiology. Patients who are small for their age may have growth delay secondary to recurrent infections, or may have short stature associated with specific T- and B-cell immunodeficiencies. A paucity of lymphoid tissue such as tonsils and lymph nodes suggests immune deficiency and is especially seen in X-linked agammaglobulinemia. Hepatosplenomegaly and diffuse lymphadenopathy might suggest HIV infection or a disorder of immune dysregulation. Certain physical findings are suggestive of specific disorders, such as with telangiectasias over the bulbar conjunctivae, the bridge of the nose, and the ears and antecubital fossa with or without ataxia in ataxia telangiectasia; chronic

KEY CONCEPTS

SCREENING TESTS FOR SUSPECTED IMMUNODEFICIENCY

- >> Evaluate for neutropenia, lymphopenia, thrombocytopenia, and/or small platelets with a complete blood count with differential and platelet count.
- >> IgG, IgA, IgM, and IgE levels. Measure of isohemagglutinin titers and of antibodies produced to vaccine antigens, such as specific antibodies to tetanus toxoid and pneumococcal polysaccharide antigens to test B-cell immune function.
- >> Lateral chest radiograph in infants, and delayed hypersensitivity skin tests (≥ 6 months of age). Consider flow cytometry to quantify T cells, T-cell subsets, B cells, and NK cells (especially in infants).
- >> Measurement of CH_{50} level.
- >> Flow cytometry of phagocytic oxidative burst using dihydrorhodamine.

CLINICAL PEARLS

DIAGNOSIS OF IMMUNODEFICIENCY

- >> Lymphopenia is a hallmark of cellular immunodeficiency in infancy. Unexplained lymphopenia should be recognized and evaluated.
- >> Normal immunoglobulin levels increase with age; age matched controls should be used for interpretation.
- >> IgG subclass levels must be interpreted in the context of the individual's clinical history and specific antibody production capabilities.

Fig. 30.3 Four-month-old infant with Chediak-Higashi syndrome. The child has oculocutaneous albinism and shunned the light of the camera because of photophobia. (Courtesy of Dr HM Rosenblatt.)

eczema in hyper-IgE syndrome, IPEX, and in Wiskott-Aldrich syndrome; chronic periodontitis in chemotactic defects of the neutrophils; and silvery hair, pale skin, and photophobia in Chediak-Higashi syndrome (Fig. 30.3). Children with LAD can present with severe gingivostomatitis and dental erosion as a consequence of abnormal leukocyte function (Fig. 30.4).

LABORATORY INVESTIGATION

The initial screen should include a complete blood count and differential with platelet determination to evaluate the total white blood cell count and total numbers of neutrophils, lymphocytes, eosinophils, and platelets. Neutropenia, lymphopenia, and abnormalities in white blood cell morphology can be detected from this study. Anemia may be present in children with chronic disease. Platelet counts may be abnormally low in children with poor bone marrow function or autoimmune disease, and platelets will be reduced in number and morphologically small in children with Wiskott-Aldrich syndrome.

Fig. 30.4 Severe gingivostomatitis and dental erosion in a 2-year-old child with LAD. (Courtesy of Dr DC Anderson.)

IMMUNOGLOBULIN LEVELS

Most evaluations of the immune system include measurement of immunoglobulin levels, including IgG, IgA and IgM. The IgA level is especially helpful in that IgA levels are low in all permanent types of agammaglobulinemia and in selective IgA deficiency. IgE level measurement is helpful when hyperimmunoglobulin E syndrome is suspected. IgG subclasses can be similarly measured. Rather than using IgG subclass levels as a screen for immunodeficiency, they are best utilized in cases of suspected subclass deficiency, such as in patients with normal IgG levels but poor functional antibody formation, or in patients with selective IgA deficiency. IgG₂ subclass deficiency has been associated with selective IgA deficiency.

Several methods are available to quantify immunoglobulin levels. The standard measure is nephelometry, which uses light scatter to measure of the rate of soluble immune complex formation in a gel.¹⁷ Another method, solid-phase enzyme-linked immunosorbent assay (ELISA), involves measurement of labeled antibody, with labels such as enzymes, fluorescent compounds and radioisotopes bound to antigen (Chapter 96). The World Health Organization has prepared reference standards for serum immunoglobulin quantification that are expressed in international units. Normal ranges of human serum immunoglobulins can vary with age (especially in children), gender, environmental factors, and race.¹⁷

SPECIFIC ANTIBODY FORMATION

To assess B-cell function, antibody production must be measured. Patients with recurrent infection may warrant this measure even if immunoglobulin levels are normal; cases of antibody deficiency have been documented in patients with normal immunoglobulin and immunoglobulin subclass

levels. An initial screen of antibody production may involve the quantification of isohemagglutinins. Isohemagglutinins occur in all individuals except those with blood type AB; they are natural IgM antibodies to polysaccharide blood group antigens A and/or B, which are not represented on the patient's red blood cells. Children less than 1 year of age do not reliably have isohemagglutinins. Individuals form this antibody as a result of environmental exposure to these ubiquitous antigens. The patient with blood type A should have anti-B; blood type B patients should have anti-A; and blood type O patients should have both anti-A and anti-B. These antibodies should normally be present in titers greater than 1:10; individuals with poor antibody production may have low or no titers.

Specific antibody production can also be measured following immunization with protein antigens, such as those derived from tetanus and diphtheria organisms, and polysaccharide antigens, such as those produced from pneumococci and *Haemophilus influenzae*. The vaccine for the unconjugated pneumococcal polysaccharide antigens is still available for immunization and is used in adults and children aged 2 years and older. Normal antibody production would include a rise in specific antibody levels within 2 weeks for protein antigens and within 4–6 weeks for polysaccharide antigens. Patients with agammaglobulinemia will have difficulty with all antibody production, whereas those with IgG₂ subclass deficiency or specific antibody deficiency with normal levels of immunoglobulin may only have difficulty with antibody production following immunization with polysaccharide antigen. Patients with selective IgA deficiency alone or with transient hypogammaglobulinemia of infancy should have normal IgG antibody production. The pneumococcal antigen challenge using the unconjugated vaccine is not recommended for children under 2 years of age because normal children do not reliably respond to the unconjugated pneumococcal antigen at this age.

Administration of a heptavalent pneumococcal conjugate vaccine, Prevnar, is now a part of the routine immunization schedule for infants and toddlers. The pneumococcal serotypes included in the vaccine, serotypes 4, 6B, 9V, 14, 18c, 19F, and 23F, are thought to be responsible for approximately 80% of invasive pneumococcal disease in children less than 6 years of age in the USA.¹⁸ Previous immunization with the conjugate vaccine does not preclude use of the unconjugated pneumococcal polysaccharide vaccine. The 23-valent polysaccharide vaccine provides the potential for stimulation and measurement of a protective immune response to 16 serotypes (1, 2, 3, 5, 7F, 8, 9N, 10A, 11A, 12F, 15B, 17F, 19A, 20, 22F, 33F) not included in the heptavalent vaccine. The IgG₁ response to the heptavalent conjugate vaccine is generally good, and elicits a protective response in infants under 2 years of age. However, when measured in a group of children with frequent episodes of otitis media, the IgG₂ response to many of the serotypes included in the vaccine remained poor.¹⁹ A booster effect was seen for the IgG₂ antibody titers of serotypes that overlap between the two vaccines when children were immunized with the 23-valent polysaccharide vaccine 6 months after having received the pneumococcal conjugate vaccine.

Patients who receive immunoglobulin replacement therapy cannot be evaluated by measurement of the above antibody levels because they are receiving the antibodies exogenously. The bacteriophage ΦX 174 can be used to evaluate such patients. The ΦX174 antigen is a nonenvironmental antigen, not experienced by the general population, and challenge with it is considered experimental. Immunization with this antigen can allow assessment of both the primary (IgM) and secondary (IgG) immune responses, and provides information regarding immune memory and ability to class switch.²⁰

LYMPHOCYTE EVALUATION

Screening tests: chest radiograph and delayed hypersensitivity skin tests

Examination of the posteroanterior and lateral chest radiographs to look for a thymic shadow can be helpful. This is especially appropriate in infants. However, the thymus may shrink in response to such stresses as surgery and infection. Cellular immune function can be screened with the use of the delayed hypersensitivity skin test. Delayed hypersensitivity reactions occur 24–48 hours or more after antigen exposure, although antigens used to test delayed hypersensitivity can also produce immediate hypersensitivity reactions. The clinical response and time of observation are used to discriminate between immediate and delayed reactions.

Histologic changes in delayed hypersensitivity initially involve the production of local edema and the dilatation of small arterioles, capillaries, venules, and lymphatics. By 4–6 hours, an infiltrate of lymphocytes and basophils is present in the perivascular areas. The perivascular changes are followed by a diffuse intervascular infiltrate of lymphocytes, basophils, and monocytes.²¹ With the tuberculin reaction, 75–90% of mononuclear cells in the perivascular aggregates are T lymphocytes or monocytes,²² and by 12–24 hours the dermal interstitium is infiltrated with T lymphocytes and monocytes. Maximal cell activation and migration with resulting induration does not occur until 48 hours after antigen exposure.

Generally, delayed hypersensitivity skin tests are performed using vaccine antigens or microbial agents to which the patient has had previous exposure. Commonly used antigens include tetanus toxoid, mumps, and extracts from *Candida albicans* and *Trichophyton*.¹⁷ The purified protein derivative (PPD) can serve as a negative control in most patients. The antigens are injected intradermally using a volume of 0.1 mL with a 25–27 gauge needle. Standard dilutions initially used are 1:100 for *Candida albicans* and tetanus toxoid, 1:10 000 for PPD, and 1:30 for *Trichophyton*. Reactions are measured at 24 and 48 hours. Rarely, severe Arthus hypersensitivity, due to circulating IgG and IgM complement-fixing antibodies, occurs ~24 hours after injection; this reaction may be manifest by warmth, erythema, edema, petechiae, and ulceration. A positive delayed hypersensitivity reaction is read as ≥5 mm of induration at 48 hours for antigens other than PPD, where an induration of 10 mm is generally required for a positive reaction.

A history of adequate previous exposure to antigen is important to obtain. Most infants less than 6 months of age will not respond. Virtually all older children and adults with previous exposure should respond to at least one antigen in a panel of PPD, mumps and *C. albicans*.²² Anergy, or nonresponse to the antigen following previous exposure, may indicate a cellular defect. A nonresponder should be retested with more concentrated antigens, or may require an *in vitro* lymphocyte evaluation in the absence of a secondary cause for anergy, such as the use of immunosuppressive therapy.

Lymphocyte enumeration

Identification of B- and T-lymphocyte subsets narrows the differential diagnosis and provides evidence for the type of combined, cellular, or antibody immunodeficiency (Chapters 34, 35, and 97). Both T and B

Fig. 30.5 Histograms of fluorescently stained lymphocytes. The quadrant of interest, A2, shows lymphocytes that are positive for labeling with both fluorescein isothiocyanate (FITC)-tagged monoclonal antibodies specific for CD3 and phycoerythrin (PE)-tagged monoclonal antibodies specific for CD4. The histogram on the left shows normal fluorescence due to CD4 T lymphocytes in quadrant A2. The histogram on the right shows absence of CD4 T lymphocytes in an infant with SCID.

cells can be identified and labeled using flow cytometry and fluorescent monoclonal antibodies. T-cell enumeration involves the use of a pan-T-cell monoclonal antibody specific for CD3. The CD4 marker serves as identification for T-helper (Th) cells. B cells can be identified by using monoclonal antibodies against the cell surface markers CD19 or CD20. Natural killer (NK) cells can be identified using monoclonal antibodies against CD16.²³ A histogram of fluorescence intensity is obtained (Fig. 30.5) from which the percentage of the specific lymphocyte subset can be obtained. A reference range is established for each subset by arranging values from the control population in order of magnitude and defining normals as those whose values fall between the fifth and 95th percentages for this population. Separate ranges should be used for children because infants and children generally have higher absolute numbers of T-cell subsets and higher percentages of CD4 cells (Fig. 30.6). Other factors, such as age, gender, and adrenocorticoid levels, can influence lymphocyte subset populations.

Lymphocyte functional analysis

To test lymphocyte function in the laboratory, lymphocyte proliferation or transformation studies are performed (Chapter 98). For these studies, lymphocytes are stimulated to proliferate involving new DNA synthesis and cell division. Lymphocytes from immunized or previously exposed individuals will proliferate in response to antigens to which they are sensitized. This response *in vitro* correlates with the *in vivo* delayed-type hypersensitivity response. Mitogens such as concanavalin A, phytohemagglutinin, and pokeweed mitogen can stimulate proliferation of normal cells, as can allogeneic histocompatibility antigens when leukocytes from two donors are mixed in culture. Proliferation of lymphocytes can be evaluated by the demonstration of transformed

lymphocytes, which resemble blasts, or by increased DNA synthesis. Increased DNA synthesis is monitored by the use of radiolabeled nucleic acid, usually tritiated thymidine, in culture media. A measure of the amount of radiolabeled material in the cells correlates with DNA synthesis.

SPECIAL TESTING

If autosomal recessive SCID is suspected, the ADA and PNP enzyme activities in the red blood cells should be determined. Recently transfused red blood cells will elevate the enzyme activity in deficient patients. White blood cells can be used to measure enzyme activity in recently transfused individuals. Ataxia-telangiectasia (AT) has the consistent laboratory finding of elevated α -fetoprotein levels along with variable abnormalities in B- and T-cell function. Molecular testing for many disorders, for example AT, X-linked SCID, Jak3 deficiency, X-linked agammaglobulinemia, LAD, and CGD, is available through commercial and research laboratories. Specialized functional tests for immune deficiency, for instance testing of lymphocyte apoptosis in a patient who may have ALPS, is available through research laboratories.

COMPLEMENT

Laboratory tests for complement components include tests for functional activity of the classic pathway with a CH₅₀ assay and the alternative pathway with an AH₅₀ assay, and immunochemical methods to measure complement component levels.²⁴ The CH₅₀ evaluation tests the ability of fresh serum from the patient to lyse antibody-coated sheep erythrocytes. This reflects the activity of all numbered components of the classic complement pathway, C1-C9, and terminal components of the alternative

Fig. 30.6 Change in distribution of peripheral blood CD4 T-cell subsets with age in healthy children. Scatter plot indicates peripheral blood CD4 T-cell counts (cells/ μ L) by age, with lowest curves in healthy children from birth to 18 years of age. (From Shearer et al. Lymphocyte subsets in healthy children from birth through 18 years of age: The Pediatric AIDS Clinical Trials Group P1009 study. *J Allergy Clin Immunol* 2003; 112: 973, with permission from the American Academy of Allergy, Asthma and Immunology.)

complement pathway. A total deficiency of one of the classic complement pathway components will result in a CH_{50} approaching zero (Chapter 20). Nephelometry, radial immunodiffusion, RIA, and ELISA are used to measure complement components. Quantitative tests for components C3 and C4 are utilized in testing for complement deficiencies and for evaluation of complement activation (Chapter 20).

PHAGOCYTES

The evaluation of a patient with a suspected phagocyte deficiency should always begin with a complete blood count. Granulocytopenia is the most frequently encountered disorder of the phagocyte system. With granulocytopenia, a qualitative neutrophil defect is unlikely and subsequent evaluation should investigate the etiology of the granulocytopenia. Neutrophilia, although most commonly associated with acute infection, is a common finding in LAD I.

Abnormalities of white blood cell function involve difficulty with adherence, locomotion, deformability, recognition, attachment, engulfment, phagosome formation, phagocytosis, degranulation, microbial killing, and elimination of engulfed material (Chapter 21). Chronic granulomatous disease is diagnosed by demonstrating absent or markedly reduced oxidase activity in neutrophils after stimulation. Flow cytometry with the conversion of dihydrorhodamine (DHR) 123 to rhodamine 123 is a sensitive assay of oxidase activity used in the diagnosis of CGD.²⁵ The nitroblue tetrazolium test (NBT) measures oxidative burst activity as well, but is more subjective and can miss the diagnosis of CGD.²⁶ For patients with suspected LAD I deficiency, purified neutrophils or monocytes are labeled with monoclonal antibody directed against a portion of the CD11/CD18 heterodimer. The sample is then further labeled with a fluorescently tagged second antibody; fluorescence is quantified by flow cytometry.²⁷

CLINICAL PEARLS

TREATMENT OF IMMUNODEFICIENCY

- >> Survival is improved and morbidity decreased in SCID patients by early transplantation.
- >> Regular intravenous or subcutaneous infusions of human immunoglobulin are the mainstay of therapy for disorders where antibody production is impaired, such as CVID, agammaglobulinemia, hyper-IgM, and some cases of AT and Wiskott–Aldrich syndrome. Delays in treatment may lead to permanent damage to organ systems, particularly the pulmonary system, where bronchiectasis or bronchiolitis obliterans may develop.
- >> The first proof of concept of gene therapy has been validated by correction of the genetic defect in X-linked SCID.

Other techniques used to identify phagocytic defects include assays for chemotaxis and bactericidal activity.

ILLUSTRATIVE CASES

CASE 1

The patient was a 6-month-old Caucasian female who presented for immunologic evaluation at 3 months of age with a history of rash and otitis media that had been recurrent since 2 weeks of age. Since birth she had had poor weight gain, frequent spitting up, coughing spells, and persistent diarrhea. There were no parental risk factors for HIV.

The physical examination showed an emaciated infant who had no palpable lymphoid tissue. The oral examination revealed white plaques consistent with thrush.

Evaluation included a radiological examination of the upper gastrointestinal tract without barium to investigate for gastroesophageal reflux, and *CFTR* gene analysis for mutations found in cystic fibrosis. Both of these were normal. Stool viral cultures were persistently positive for rotavirus.

Immunodeficiency was suspected because of the failure to thrive, persistent chronic diarrhea, and recurrent infection. An evaluation of the immune system was performed (Table 30.2). Humoral immunity was first tested with immunoglobulin levels. All were below or just above the lower limit of normal. Isohemagglutinins were not tested as the patient was less than 1 year old. As she had not been immunized, specific antibody titers to vaccines were not tested. Stool α_1 -antitrypsin levels were normal, suggesting that protein was not being lost in the stool, and urinalysis did not show protein loss. The complete blood count revealed profound lymphopenia and absolute neutropenia. The neutropenia resolved on subsequent evaluations but the lymphopenia persisted. The thymic shadow was not present on chest radiograph (this finding is not unusual in children with chronic illness, in whom the thymus may involute). Delayed hypersensitivity skin tests were not placed as the patient would not have been expected to have a reliable response at this age. Evaluation of lymphocytes subsets by flow cytometry revealed that the CD4 and CD8 T- and B-lymphocyte numbers were all markedly low.

The patient's lymphocytes had no proliferative response when stimulated with phytohemagglutinin. The history and physical examination, along with the laboratory values, including low immunoglobulin levels and markedly low lymphocyte numbers with poor proliferative response to mitogen stimulation, strongly suggested the diagnosis of SCID. The patient had low levels of adenosine deaminase (ADA) and increased levels of the metabolites of ADA. Severe combined immunodeficiency secondary to ADA deficiency was diagnosed.

Following ADA replacement therapy and immunoglobulin infusions the patient has thrived and has had fewer infections. Lymphocyte numbers and function have improved.

CASE 2

A 5-week-old African-American female infant who was perinatally exposed to HIV-1 was admitted to the hospital for cough, poor weight gain, and vomiting.²⁷ She did not have a rash, thrush, diarrhea or fever. She had been a term delivery with normal birthweight and developed a nonproductive cough at 2 weeks of age. Her mother had received highly active antiretroviral therapy during pregnancy, zidovudine was given intrapartum, and the infant had received zidovudine orally since birth. The physical examination showed mild thrush, no adenopathy, and no hepatosplenomegaly or rash. A chest radiograph showed diffuse nodular infiltrates in both lungs. An upper gastrointestinal radiographic series showed gastroesophageal reflux.

Laboratory results showed an increased white blood cell count, eosinophils, absolute lymphocyte count, and normal immunoglobulins. Percentages of T cells and CD4 T cells were elevated, and B-cell percentages were at the low end of normal. An HIV DNA PCR was negative. A NBT test demonstrated absence of dye reduction in all cells compared to control cells. Immunoblot analysis of neutrophil lysates probed for each of the four structural components of the NADPH oxidase complex demonstrated deficiency of the p47^{phox} component (Fig. 30.7), confirming autosomal recessive CGD. A lung biopsy showed granulomatous inflammation consisting of epithelioid histiocytes, multinucleated giant cells, and rare and degenerating fungal hyphae by silver stain. The patient received a 40 mg/kg cumulative dose of amphotericin B and was then started on itraconazole to receive a total of 6 months of antifungal therapy for presumed *Aspergillus* species pneumonia. She receives trimethoprim-sulfamethoxazole prophylaxis, interferon- γ injections, and itraconazole secondary prophylaxis and is currently thriving. Her sibling is not an HLA match.

CASE 3

The patient was a 12-year-old Caucasian male who presented at 8 months of age with diarrhea for 1 month, nuchal rigidity, left facial weakness, and a left sixth cranial nerve palsy. He had been well for the first 6 months of life. The family history was negative for immunodeficiency. The patient had received the childhood immunizations that were routine at that time, including the live polio virus vaccine at 2, 4, and 6 months of age.

Physical examination revealed an absence of tonsillar tissue, and the patient had no palpable lymph nodes. The presenting neurologic symptoms resolved, but the patient subsequently developed a lower-extremity flaccid paralysis that has persisted.

Fig. 30.7 Immunoblot analysis in a case of autosomal recessive CGD. Immunoblot analysis of neutrophil lysates probed for each of the four structural components of the NADPH oxidase complex demonstrating deficiency of the p47^{phox} component. (From Seeborg et al. A five-week-old HIV-1-exposed girl with failure to thrive and diffuse nodular pulmonary infiltrates. *J Allergy Clin Immunol* 2004; 113: 632, with permission from Elsevier.²⁸)

The cerebrospinal fluid was remarkable for a lymphocytic pleocytosis with normal protein and glucose levels. Stool and throat cultures grew vaccine strain poliovirus.

Immunodeficiency was suspected because of the chronicity of the illness, the lack of lymphoid tissue on physical examination, and the finding of an unusual infectious agent causing severe sequelae to infection. The age at presentation was typical for patients with a defect in humoral immunity.

Immune system evaluation (Table 30.2) included a complete blood count that showed a normal absolute neutrophil count and a low absolute lymphocyte count. The CH₅₀ was mildly elevated; this result eliminated a complement component deficiency from the differential diagnosis. The oxidative burst assay was normal. Initial immunoglobulin levels were low. Isohemagglutinin titers were negative (this result is difficult to interpret, as normal patients under 1 year of age will not reliably have isohemagglutinins present). Antibody levels to diphtheria and tetanus were very low. The thymus was present on the chest radiograph. Delayed hypersensitivity skin tests were negative. *In vitro* lymphocyte evaluation showed normal numbers and percentages of T lymphocytes and decreased numbers and percentages of B lymphocytes. The presence of decreased B lymphocytes ruled out transient hypogammaglobulinemia of infancy, in which B lymphocytes are normal in number and specific antibody production is normal. Proliferative responses of lymphocytes to mitogens were normal. Molecular testing has shown a mutation in the gene encoding Bruton's tyrosine kinase (BTK). The patient was diagnosed with vaccine acquired polio virus infection and X-linked agammaglobulinemia.

Table 30.2 Results of screening tests and special evaluations of illustrative cases. Normal values are reported in parentheses. Normal values may vary from laboratory to laboratory due to technique and may vary owing to age

^cNormal values taken from Shearer WT et al. Lymphocyte subsets in healthy children from birth through 18 years of age: The Pediatric AIDS Clinical Trials Group P1009 study. J Allergy Clin Immunol 2003; 112: 973.

^dSame-day normal control values performed by the Immunology Laboratory at Texas Children's Hospital.

ND, not done.

The patient receives monthly immunoglobulin replacement therapy. Subsequent infections have included recurrent otitis media, conjunctivitis, and sinusitis.

CASE 4

The patient presented at 3 years of age following hospitalization for pneumonia. The past medical history was significant for recurrent otitis media and bronchitis. The family history was negative for diagnosed immunodeficiency, although two siblings had had a history of recurrent otitis media and bronchitis. The patient had had normal growth and development.

The physical examination revealed normal tonsillar tissue in the posterior pharynx and the presence of small lymph nodes in the cervical region.

Laboratory values (Table 30.2) included a normal white blood cell count with normal numbers of granulocytes and lymphocytes. The chest radiograph showed the presence of a thymic shadow. Cellular immune function was tested with delayed hypersensitivity skin testing which was positive for *C. albicans* antigen and tetanus toxoid, and negative for purified protein derivative. Serum immunoglobulin levels were normal. The patient had been previously immunized and had adequate antibody titers to tetanus toxoid, diphtheria, and pneumococcus, suggesting the ability to form antibody when challenged. Isohemagglutinins were also positive.

The CH₅₀ level was below the lowest measurable level. C3 and C4 levels were normal, but the level of C2 was 0. The patient's father, mother, and brother had levels of C2 which were half of the normal value, indicating that they were heterozygotes for the abnormal C2 allele.

C2 deficiency was diagnosed. The patient is now 7 years old and has chronically had sinusitis and bronchitis. C2 deficiency is frequently associated with autoimmune disease; this patient has no current autoimmune disease but receives yearly surveillance examinations.

Infections in the immunocompromised host

Michael C. Sneller, H. Clifford Lane

31

INTRODUCTION

The term 'compromised host' refers to an individual who has one or more defects in the body's natural defense mechanisms which are of sufficient severity to predispose the host to life-threatening infection. Defects in host defense mechanisms that render an individual 'compromised' include: (1) damage to anatomical barriers (i.e., the skin and mucosal surfaces); (2) quantitative or qualitative defects of phagocytic cells; (3) defects in humoral immunity; and (4) defects in cell-mediated immunity. Specific host defense abnormalities are associated with increased susceptibility to infection with certain pathogens (Table 31.1). Except for certain humoral immune deficiencies, these defects rarely exist in isolation and in most clinical situations more than one defect in host defense is present. In this chapter, infections seen in the compromised host are categorized and discussed in terms of the dominant immunologic defect present.

INFECTIONS IN PATIENTS WITH PHAGOCYTE DEFECTS

The neutrophil and monocyte are phagocytic cells that constitute a major component of the host defense against invasive bacteria and fungi. The neutrophil is the predominant phagocytic cell in the peripheral circulation and significant deficiencies in either neutrophil number or function are invariably associated with bacterial and fungal infections. In contrast, neutropenia *per se* does not appear to increase the risk or severity of viral, mycobacterial, or parasitic infections.

QUANTITATIVE ABNORMALITIES OF PHAGOCYTES

The most commonly encountered phagocytic defect is a decrease in the absolute number of circulating neutrophils. Acquired neutropenia is usually the predictable result of cytotoxic therapy for autoimmune or malignant disease. Neutropenia may also result from idiosyncratic reactions to drugs such as chloramphenicol, phenothiazines, sulfonamides, penicillins, cephalosporins, and vancomycin. Other causes of

KEY CONCEPTS

The types of infections that occur in the compromised host are determined by the specific immunological defects present.

- >> Phagocytic cells constitute a major component of the host defense against invasive bacterial and fungal pathogens. Significant deficiencies in either phagocytic cell number or function are invariably associated with bacterial and fungal infections
- >> Immunoglobulin and complement are the two main components of the humoral immune system and function to protect the host from infection with extracellular pathogens. Antibody and complement deficiency syndromes are primarily associated with recurrent bacterial infections with encapsulated, extracellular bacteria
- >> Defects in cell-mediated immunity are primarily associated with infections due to viruses and intracellular pathogens
- >> In most clinical situations more than one abnormality of host defense is present

acquired neutropenia include abnormal sequestration or destruction of neutrophils by the spleen, which can be mediated by immunoglobulin G (IgG) anti-neutrophil antibodies or result from hypersplenism of any cause.

The normal lower limit for circulating neutrophils is 1500–2000 cells/mm³, except in the newborn period (< 1 week of age), when it is 5000 cells/mm³ and infancy (< 1 year of age), when it is 1000 cells/mm³. As counts fall below 500 cells/mm³ there is a progressive increase in serious infections that correlates with both the magnitude and duration of neutropenia. With neutrophil counts below 100 cells/mm³, the incidence of infection increases dramatically.¹ While the depth and duration of neutropenia are the predominant determinants of susceptibility to infection, other factors may also influence the frequency and pattern of infections. Such factors include: the patient's endogenous bacterial and fungal flora;

^aSee text for details and exceptions.

disruption of the integrity of mucosal barriers by cytotoxic chemotherapy (e.g., oral mucositis); concurrent abnormalities of cellular or humoral immunity (related to the underlying disease or its therapy); and the presence of indwelling intravenous catheters. Thus, patients who have received cytotoxic chemotherapy for the treatment of malignant disease may have a higher frequency of infections than patients with equivalent degrees of neutropenia secondary to idiosyncratic drug reactions or aplastic anemia.

The microbiology of bacterial infections in the neutropenic host has changed significantly over the past 20–25 years. In the 1970s Gram-negative bacilli (e.g., *Escherichia coli*, *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*) were the most frequently identified bacterial pathogens in patients with chemotherapy-induced neutropenia.² By the 1980s, the routine use of empiric antibiotic therapy targeted primarily at Gram-negative pathogens led to the emergence of Gram-positive organisms as the predominant bacterial pathogens isolated from neutropenic cancer patients.³

Although virtually any bacterial organism is a potential pathogen in the neutropenic host, the Gram-negative organisms most frequently

isolated from blood cultures of febrile neutropenic cancer patients are *E. coli*, *K. pneumoniae*, and *P. aeruginosa*. Other Gram-negative pathogens, such as *Enterobacter* and *Citrobacter* species, are less commonly isolated from these patients.³ A clinically apparent source for Gram-negative bacteria is not usually identified, and it is presumed that these infections originate from occult sites in the gastrointestinal tract, respiratory tract, urinary tract, or soft tissues.

The Gram-positive organisms most often isolated include coagulase-negative staphylococci, *Staphylococcus aureus*, enterococci, and alpha-hemolytic streptococci. *S. aureus* and coagulase-negative staphylococci are most often isolated from the bloodstream in patients with indwelling central venous catheters. Bacteremia with *S. aureus* or alpha-hemolytic streptococci tends to be clinically aggressive in neutropenic patients and is frequently associated with cardiovascular collapse and shock while infections with coagulase-negative staphylococci tend to be more indolent. Other Gram-positive bacteria that are occasionally isolated include *Bacillus* species and *Corynebacterium jeikeium*. Infections with both of these organisms are associated with indwelling vascular catheters.

Pure infections with anaerobic bacteria are unusual in neutropenic patients and are invariably associated with breaches of the gastrointestinal mucosa. Mixed aerobic-anaerobic infections are usually seen in patients with intra-abdominal processes or perirectal soft-tissue infections.

Invasive fungal infections are a major cause of morbidity and mortality in the neutropenic host. Systemic fungal infections are rarely the cause of primary infections in neutropenic patients not receiving antibiotics and seen less frequently in patients with 'short-term' (< 14 days) neutropenia. Risk factors for the development of invasive fungal infections include prolonged (> 14 days) neutropenia, broad-spectrum antibiotic therapy, and concurrent glucocorticosteroid use. Of these factors, severe and prolonged neutropenia is the most important.⁴ Although a wide variety of fungi can cause invasive infection in the neutropenic host, *Candida* and *Aspergillus* species are the most common pathogens encountered. The predominance of *Candida* and *Aspergillus* infections in this clinical setting attests to the importance of the neutrophil in controlling infections due to these two organisms.

The most frequent *Candida* species causing disseminated infection is *C. albicans*. Other potential *Candida* pathogens include *C. tropicalis*, *C. parapsilosis*, *C. glabrata*, and *C. krusi*. In neutropenic patients *Candida* may cause local infection of the oral cavity, esophagus, vagina, or lower gastrointestinal tract; catheter-related candidemia; or disseminated infection with involvement of the liver and spleen (hepatosplenic candidiasis), skin, or eye (endophthalmitis). The *Aspergillus* species that most frequently infect neutropenic patients are *A. fumigatus* and *A. flavus*. *Aspergilli* are ubiquitous in nature and infection is acquired primarily through the respiratory tract. The upper airways (nasal cavity and sinuses) and lung are the primary sites of invasive infection in neutropenic patients. *Aspergillus* usually spreads by direct invasion to contiguous tissue (Fig. 31.1), although widespread (presumably hematogenous) dissemination to the skin, kidneys, and brain can occur. Blood cultures are virtually never positive for *Aspergillus* and the diagnosis is made by biopsy and culture of the affected tissue. Other fungal pathogens that can cause invasive infection in neutropenic hosts include members of the order Mucorales (*Mucor*, *Rhizopus*, *Cunninghamella*), *Trichosporon beigelii*, *Fusarium* species, *Drechslera* species, *Pseudoallescheria boydii*, and *Malassezia furfur*.

Because neutropenia impairs the local inflammatory response to infection, fever is often the initial and only manifestation of serious infection. Approximately 20% of febrile episodes in patients with neutrophil counts below 100 cells/mm³ will be associated with bacteremia¹ which, if left untreated, can be rapidly progressive and lethal. These considerations serve as the basis for the expeditious use of empiric broad-spectrum antibiotic therapy in patients with fever and neutropenia. The initial evaluation of the febrile neutropenic patient should begin with a thorough physical examination paying particular attention to the oral cavity, perianal region, and the site of any indwelling intravenous catheter. Blood and urine cultures should be obtained and other sites of potential infection should be evaluated by biopsy or aspiration as clinically indicated. Once the initial evaluation is complete, empiric broad-spectrum antibiotic therapy should be initiated. A number of single- or multiple-agent regimens have been successfully used. The initial selection of antibiotics should be based on the institutional antimicrobial sensitivity patterns of the most likely pathogens and the clinical findings. Modification of the initial antibiotic regimen is often necessary and should be based on culture results and frequent monitoring of the patient by physical examination. Detailed guidelines for antimicrobial therapy in neutropenic hosts have been published by the

Fig. 31.1 Chest computed tomography scan of a patient with chronic granulomatous disease and pulmonary infection with *Aspergillus fumigatus*. The infection has spread by direct extension to involve the adjacent thoracic vertebral body and rib, and has partially destroyed these structures.

Infectious Diseases Society of America.⁵ Results from several randomized trials suggest that selected low-risk hospitalized patients with fever and neutropenia that is expected to last less than 10 days can be safely treated with an oral antibiotic regimen.⁵

The diagnosis of invasive fungal disease in the neutropenic host is difficult. The neutropenic patient with persistent or recurrent fever after 5–7 days of antibiotic therapy is at particular risk for invasive fungal superinfection. By the time an invasive fungal infection becomes clinically apparent it is usually far advanced and difficult to treat. These considerations, along with the results of two controlled trials,⁶ initially led to the routine use of empiric antifungal therapy with amphotericin B in patients with persistent or recurrent fever after 5–7 days of antibiotic therapy. In subsequent studies, liposomal amphotericin B, voriconazole, and caspofungin all appear to be as effective as conventional amphotericin B for empirical antifungal therapy in these patients, and are associated with less toxicity.⁷

A recent advance in therapy for quantitative phagocytic defects has been the use of recombinant hematopoietic growth factors to shorten the duration of neutropenia in patients treated with cytotoxic chemotherapy. Of these factors, the most widely studied are granulocyte and granulocyte-macrophage colony-stimulating factors (G-CSF and GM-CSF respectively). These glycoproteins stimulate the growth and maturation of hematopoietic progenitor cells and increase the number and function of committed phagocytic cells. Both G-CSF and GM-CSF have been shown to accelerate granulocyte recovery following cytotoxic chemotherapy.⁸

QUALITATIVE ABNORMALITIES OF PHAGOCYTES

The ability of phagocytic cells to ingest and kill microorganisms involves a complex series of biochemical events. At the cellular level, these events involve the migration of phagocytic cells to the inflammatory site (chemotaxis), cell activation, phagocytosis, and the killing of organisms by oxidative-dependent and independent pathways. Primary defects in

any of these steps can be associated with recurrent and severe bacterial or fungal infections. A detailed discussion of the pathogenesis, diagnosis, and management of phagocyte deficiencies is presented in Chapter 21.

■ INFECTIONS IN PATIENTS WITH DEFECTS IN THE HUMORAL IMMUNE RESPONSE – IMMUNOGLOBULIN AND COMPLEMENT ■

Immunoglobulins and complement are the two main components of the humoral immune system. The primary role of the humoral immune system is to protect the host from extracellular pathogens. The binding of specific antibody to microbial antigens facilitates the clearing of extracellular pathogens by a variety of effector mechanisms that are dependent on the immunoglobulin isotype (Chapter 15). These mechanisms include: opsonization of organisms for ingestion and intracellular destruction by phagocytic cells; cell-free lysis of susceptible organisms by interaction with the complement system; neutralization of microbial toxins; and inhibition of the attachment of microorganisms and extracellular viruses to host cells. Once an organism is intracellular, it is no longer accessible to antibody or complement molecules. However, intracellular organisms may modify the surface proteins of infected host cells and stimulate an antibody response to these cells. Such a response can recruit the cellular immune system and lead to the destruction of infected cells by antibody-dependent cellular cytotoxicity (ADCC).

PRIMARY IMMUNOGLOBULIN DEFICIENCY SYNDROMES

Significant deficiency of antibody production occurs in a number of primary immunodeficiency syndromes. Antibody deficiency syndromes can be congenital or apparently acquired and be associated with deficiencies in all or in only some immunoglobulin isotypes (Chapter 34). IgG is the major heat-stable opsonin of extracellular fluid, and syndromes associated with significant IgG deficiency (i.e., X-linked agammaglobulinemia, hyper-IgM syndrome, and common variable immunodeficiency) are invariably associated with recurrent infections. Clinically, patients with hypogammaglobulinemia present with recurrent bacterial infections of the respiratory tract, such as sinusitis, otitis media, bronchitis, and pneumonia. The most common etiologic agents are encapsulated, extracellular bacteria such as *Streptococcus pneumoniae* and *Haemophilus influenzae*. The occurrence of repeated infections with encapsulated bacteria in IgG-deficient patients illustrates the importance of IgG in host defense against these pathogens. If hypogammaglobulinemia goes undiagnosed (and hence untreated), recurrent pulmonary infections can lead to irreversible chronic lung disease with bronchiectasis. In such patients the spectrum of bacterial pathogens is broader and includes *Staphylococcus aureus* and *Pseudomonas aeruginosa*. Septicemia and recurrent infections of the skin, urinary tract, joints, or central nervous system (CNS) also occur in patients with hypogammaglobulinemia, but are less frequent.⁹

Opportunistic infections are uncommon in patients with X-linked agammaglobulinemia and common variable immunodeficiency. However, rare cases of *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) have

been reported in patients with hypogammaglobulinemia and apparently normal T-cell function. The classic X-linked hyper-IgM syndrome results from mutations in the gene encoding CD40 ligand (CD 154). Immunologic manifestations of this syndrome include hypogammaglobulinemia, normal or elevated serum IgM, and defective cell-mediated immunity.¹⁰ In addition to recurrent bacterial infections, these patients can develop infections with opportunistic pathogens such as *Toxoplasma gondii*, *P. jiroveci*, and *Cryptosporidium*.

Patients with hypogammaglobulinemia confront viral infections normally, but there are some exceptions. Frequent and severe recurrences of herpes simplex infections have also been reported in a small number of patients with common variable immunodeficiency, as have severe cytomegalovirus (CMV) infections. Patients with X-linked agammaglobulinemia are at increased risk of developing paralytic poliomyelitis following live poliovirus vaccination. This complication has largely been eliminated by the use of inactivated poliovirus (Salk vaccine) in early-childhood immunization.

An unusual syndrome of severe enteroviral infection is seen in patients with primary antibody deficiency syndromes.¹¹ This type of infection is most commonly associated with X-linked agammaglobulinemia, but several well-documented cases have occurred in patients with common variable immunodeficiency. The most common pathogens are echoviruses, especially echovirus type 11. Patients usually present with a meningoencephalitis that runs a chronic, progressive, and usually fatal course. Some patients may also have extraneurologic manifestations of disseminated enteroviral infection, including fever, a dermatomyositis-like syndrome, and hepatitis. In a few cases these manifestations have preceded the development of neurological symptoms. This syndrome is best diagnosed by examination of the cerebrospinal fluid. Patients almost always have elevated cerebrospinal fluid protein and a lymphocytic pleocytosis and, frequently, cerebrospinal fluid culture is positive for enterovirus. The fact that this syndrome of chronic enteroviral infection is only seen in patients with hypogammaglobulinemia provides firm evidence that the humoral immune system plays an important role in the host defense against enteroviral infections.

Patients with hypogammaglobulinemia suffer from a variety of gastrointestinal infections. The protozoan *Giardia lamblia* is a common cause of infectious diarrhea in these patients. In normal hosts, *Giardia* usually causes a self-limited, mild diarrheal syndrome lasting for days to weeks. In contrast, patients with hypogammaglobulinemia frequently develop chronic diarrhea with significant malabsorption and weight loss that may last for months to years. Patients with hypogammaglobulinemia are also at increased risk for infection caused by bacterial enteric pathogens such as *Salmonella*, *Shigella*, and *Campylobacter* species.

The association of recurrent infections and selective deficiency of IgA is less strong. Selective IgA deficiency is the most common form of immunoglobulin deficiency, with a reported frequency of 1 in 700 individuals.¹² Most IgA-deficient individuals are healthy and do not suffer from abnormally severe or frequent infections. However, for reasons that are unclear, certain IgA-deficient patients appear to suffer from increased numbers of upper respiratory infections.

Although usually classified as a disorder of neutrophil function, the hyper-IgE with recurrent infections syndrome (Job's syndrome) is a complex immunoregulatory disorder characterized by elevated serum IgE levels, chronic dermatitis, and serious recurrent bacterial infections

of the lower respiratory tract and skin. Job's syndrome is not a humoral immunodeficiency *per se*, but is a syndrome in which abnormal regulation of the humoral response may lead to recurrent infections. A detailed description of Job's syndrome is presented in Chapter 21.

IMMUNOGLOBULIN DEFICIENCY SYNDROMES ASSOCIATED WITH LYMPHOID MALIGNANCIES

Impaired antibody responses are associated with several lymphoid malignancies. Multiple myeloma is associated with both decreased synthesis and increased metabolism of normal immunoglobulin that results in an impaired antibody response to encapsulated bacteria. The degree of humoral immunodeficiency increases with the tumor burden. In the absence of chemotherapy and neutropenia, infections in patients with multiple myeloma are largely due to encapsulated bacteria such as *Streptococcus pneumoniae* and *Haemophilus influenzae*.

Advanced chronic lymphocytic leukemia (CLL) is frequently associated with hypogammaglobulinemia. The vast majority of infections in CLL are similar to those seen in primary hypogammaglobulinemia (i.e., sinopulmonary infections due to encapsulated bacteria). Patients with advanced disease may require splenectomy, which puts them at further risk for severe infections with *S. pneumoniae*.

Hodgkin's disease has been associated with *in vitro* abnormalities of T-cell function and impaired delayed hypersensitivity skin tests. However, the types of infections seen in nonneutropenic patients with Hodgkin's disease are more consistent with an abnormality of humoral immunity. In a series of 300 consecutive patients with Hodgkin's disease, *S. pneumoniae* was the most common organism causing microbiologically documented serious infection.¹³ In this study, serious infections with encapsulated extracellular bacteria were predominantly seen in those patients who had received prior treatment with combined radiation and chemotherapy for relapses of their disease, a finding also documented in other studies.¹⁴

COMPLEMENT DEFICIENCIES

A number of primary deficiencies of various complement components have been described (Chapter 20). Deficiencies in the early complement proteins (C1, C2, C4) are not usually associated with recurrent infections but are associated with syndromes of immune overactivity such as systemic lupus erythematosus and angioedema. In contrast, deficiencies of C3 and C5–9 are frequently associated with severe bacterial infections. C3 deficiency has been linked to severe and recurrent infections with *S. pneumoniae*, *H. influenzae* and *Neisseria meningitidis*, while deficiencies of C5–9 are associated with severe infections due to *N. gonorrhoeae* and *N. meningitidis*.¹⁵ Infections with enteric Gram-negative bacteria and staphylococci are also seen. Although the defects in the late complement components may be present from birth, recurrent and severe infections (especially with *Neisseria* species) typically do not begin until the teenage years. Any patient with recurrent infections due to *Neisseria* species should be investigated for complement deficiency.

SPLENECTOMY

The spleen has at least two major roles in host defense. First, the spleen serves as a source for antibody production. Second, the anatomy of the spleen is such that it serves as a filter capable of removing bacteria from the bloodstream through its mononuclear phagocytic cells. The spleen is

particularly efficient at clearing nonopsonized bacteria. Although surgical removal of the spleen is not clearly associated with an increased susceptibility to infection, certain infections can be much more severe in splenectomized individuals. The only clinical syndromes that clearly occur more frequently following splenectomy are severe hemolysis due to infection with *Babesia* species and the syndrome of overwhelming sepsis due to *S. pneumoniae* and other encapsulated bacteria. Despite the large amount of published literature on this subject, insufficient data are available to determine the true incidence, pathogenesis, and exact risk factors for either syndrome.

Approximately 5% of individuals undergoing splenectomy for hematological malignancy, hemolytic anemia, or thalassemia will develop overwhelming septicemia.¹⁶ Patients with splenectomy due to traumatic rupture are at a much lower risk. In addition, children are at higher risk for overwhelming *S. pneumoniae* or *H. influenzae* septicemia than adults.¹⁶ Presumably this is because adults have had prior exposure to the encapsulated organisms and have pre-existing humoral immunity which compensates for the lack of a spleen. This underscores the need for immunization with pneumococcal and *H. influenzae* vaccines in patients about to undergo splenectomy.

Babesiosis is an infection by a malaria-like protozoa (*Babesia*) that parasitizes erythrocytes. Most infections in normal hosts are asymptomatic. However, babesiosis in splenectomized individuals may be associated with fever, severe hemolysis, and hemoglobinuria.¹⁷

INFECTIONS IN PATIENTS WITH PRIMARY CELLULAR AND COMBINED IMMUNODEFICIENCY SYNDROMES

SEVERE COMBINED IMMUNODEFICIENCY DISORDERS (SCID)

The syndromes of SCID are characterized by great diversity at the cellular, molecular, and genetic level (Chapter 35). Regardless of the molecular defect, patients with SCID exhibit an absence of all adaptive immunity from birth. There is profound lymphopenia, hypogammaglobulinemia, and absent *in vitro* B- and T-lymphocyte responses to antigens and mitogens. Most patients exhibit failure to thrive and develop abnormal infections during the first months of life. These patients develop infections characteristic of defects in both humoral and cell-mediated immunity. Infections frequently seen include: bacterial pneumonia and septicemia due to *Staphylococcus aureus*, *Streptococcus pneumoniae*, and *H. influenzae*; *P. jirovecii* pneumonia, cutaneous and systemic infections with *Candida*; and disseminated infection with herpes group viruses.

PARTIAL CELLULAR AND COMBINED IMMUNODEFICIENCY DISORDERS

Thymic hypoplasia (DiGeorge syndrome) results from developmental abnormalities of the third and fourth pharyngeal pouches during embryogenesis that results in aplasia or hypoplasia of the thymus and parathyroid glands¹² (Chapter 35). Congenital cardiac abnormalities can also be seen. Cardiac and parathyroid complications often alert the physician to the presence of this syndrome before recurrent infections appear. Serum immunoglobulin concentrations are usually normal or near normal for age, but IgA deficiency can be present. T-cell numbers

are markedly decreased, as are *in vitro* responses to T-cell mitogens. Infectious diseases associated with this syndrome include chronic mucocutaneous candidiasis, and recurrent pneumonia (*P. jiroveci*).

The Wiskott–Aldrich syndrome (WAS) is an X-linked syndrome characterized by eczema, thrombocytopenic purpura, and increased susceptibility to infections¹⁸ (Chapter 35). The immunologic defect most consistently found in these patients is a profound inability to mount a normal antibody response to polysaccharide antigens. Serum immunoglobulin levels are variable, but most patients exhibit low IgM, elevated IgA and IgE, and normal levels of IgG subclasses. T lymphocytes in the peripheral blood of WAS patients exhibit a progressive decline in number and function such that, by 6 years of age, profound lymphopenia is usually present. This pattern of immunologic abnormalities correlates with the types of infections seen in WAS. In younger patients, infections are predominantly due to encapsulated bacteria such as *S. pneumoniae*, *H. influenzae*, and other bacteria having polysaccharide capsules. Otitis media, pneumonia, meningitis, and sepsis are the most frequent types of infections caused by these organisms. Later in life, children with WAS develop opportunistic infections with agents such as *P. jiroveci* and Herpesviridae.

Ataxia-telangiectasia is a rare multisystem disease that generally presents in the first 3 years of life and culminates in death by the second decade¹² (Chapter 35). The most prominent clinical manifestations of this syndrome are cerebellar ataxia, oculocutaneous telangiectasias, chronic sinopulmonary infections, a high incidence of malignancy, and variable defects in humoral and cell-mediated immunity. Patients with ataxia-telangiectasia exhibit variably decreased levels of total IgG, IgG₂, IgA, and IgE. *In vitro* there is a decrease in mitogen-induced immunoglobulin synthesis that can be corrected by the addition of normal T cells. Clinically, this defect in humoral immunity is manifested by recurrent sinopulmonary infections with encapsulated bacteria. Cellular immunity is only mildly depressed at birth, but progressive impairment of delayed-hypersensitivity skin reactions and *in vitro* T-cell proliferative responses is noted in older children. Despite these defects in cellular immunity opportunistic viral, fungal, and parasitic infections are uncommon.

HIV INFECTION AND AIDS

Human immunodeficiency virus (HIV) infection leads to the progressive destruction of CD4 lymphocytes, resulting in immunodeficiency.¹⁹ This occurs in a setting of immunosuppression due to immune system activation characterized by increased T-cell turnover and polyclonal B-cell activation. Patients with HIV infection become increasingly at risk for opportunistic infections as the CD4 T-cell count declines and/or as the levels of HIV in the blood increase. While the majority of these infections are reflective of decreased T-cell function, patients with HIV infection are also at risk for a variety of other infections as a consequence of either aberrant antibody production or drug-induced neutropenia. Recent advances in anti-retroviral therapy have led to a precipitous drop in the incidence of acquired immunodeficiency syndrome (AIDS)-defining opportunistic infections in the more developed parts of the world (Fig. 31.2).¹⁹ Unfortunately these advances are not available to all patients with HIV infection and despite these advances, secondary infections remain a leading cause of death for patients with HIV infection and AIDS.

HIV infection can be classified into different stages depending upon the CD4 T-cell count and the clinical stage of disease (Table 31.2)

Fig. 31.2 Rates of opportunistic illness among human immunodeficiency virus (HIV)-infected patients with fewer than 100 CD4 T cells per cubic millimeter, from 1992 through 1998. (Adapted and updated from Palella FJ, et al, *New England Journal of Medicine* 1998; 338: 853–860 and Kaplan et al, *Clinical Infectious Diseases* 2000; Suppl. 1 Vol. 30: S5–S14.

(Chapter 37). This staging system utilizes the CD4 T-cell count for categories 1, 2, and 3 and the clinical stage for categories A, B, and C. Acute HIV infection (category A) may present with a clinical syndrome characterized by fever, lymphadenopathy, pharyngitis, arthralgias/myalgias, and rash.¹⁹ In some patients this is associated with a precipitous drop in CD4 T-cell count, and opportunistic infections such as esophageal candidiasis can be seen during this time. Generally, however, patients with HIV infection remain free of secondary infections until the CD4 T-cell count falls below 500 cells per cubic millimeter (categories 2 and 3). The asymptomatic period of HIV disease following primary infection is referred to as stage B. The development of secondary diseases denotes progression to stage C.

Once the CD4 T-cell count falls below 500 cells/mm³, but remains above 200 cells/mm³, a variety of minor secondary infections can be seen (Table 31.3). These infections appear more common in patients with higher viral loads and include mucosal candidiasis, condyloma acuminata, oral hairy leukoplakia, and localized reactivation of herpes zoster (shingles) and herpes simplex. Patients with CD4 T-cell counts below 200 cells/mm³ are at risk for a wide variety of opportunistic infections (Table 31.3).

PROTOZOAL INFECTIONS

Protozoal infections are among the most common life-threatening secondary infections in patients with HIV infection. Toxoplasmosis is the most common secondary infection of the nervous system in patients with AIDS. Other protozoal infections of the CNS include focal CNS lesions due to *Trypanosoma cruzi* and meningoencephalitis due to *Acanthamoeba* spp. or *Naegleria* spp. Toxoplasmosis is generally a late complication of HIV infection and is more common in patients from the Caribbean or from France. CNS toxoplasmosis is thought to represent a reactivation

Table 31.2 1993 revised classification system for human immunodeficiency virus (HIV) infection and expanded acquired immunodeficiency syndrome (AIDS) surveillance case definition for adolescents and adults

CD4 T-cell category	Clinical categories		
	A Asymptomatic, acute (primary) HIV or PGL	B Symptomatic, not A or C conditions	C AIDS indicator conditions
> 500/ μ l	A1	B1	C1
200–499/ μ l	A2	B2	C2
< 200/ μ l	A3	B3	C3

PGL, progressive generalized lymphadenopathy.
(From: Morb Mort Week Rep 42, No. RR-17, December 18, 1992.)

syndrome and is 10 times more common in patients seropositive for antibodies to the etiologic agent, *Toxoplasma gondii*. In patients with AIDS, toxoplasmosis generally presents as a seizure or focal neurologic defect in association with fever. The presumptive diagnosis is based upon a magnetic resonance imaging, or double-dose contrast computed tomographic finding of multiple contrast-enhancing lesions in multiple locations (Fig. 31.3). Both *T. gondii* and trypanosomiasis can also involve the myocardium.

Protozoal infections, particularly *Cryptosporidium* and *Microsporidium* spp., can also cause diseases of the gastrointestinal tract in patients with HIV infection.²⁰ These organisms are responsible for clinical syndromes ranging from mild diarrhea to severe diarrhea with dehydration, nausea, and vomiting. *Cryptosporidium* can also involve the biliary tree. In addition to these two organisms one may also see diarrheal illness due to *Isospora belli*. This is an important diagnosis to make, given the fact that infection with *Isospora*, in contrast to infection with *Microsporidium* or *Cryptosporidium*, is relatively easy to treat and responds well to the combination of trimethoprim/sulfamethoxazole or ciprofloxacin.

Visceral leishmaniasis is recognized with increasing frequency in patients with HIV infection who live or travel to endemic areas. The clinical presentation is usually one of hepatosplenomegaly, fever, lymphadenopathy, and hematologic abnormalities. This disease is transmitted by sandflies. Patients usually respond well to standard therapy with pentavalent antimony compounds.

BACTERIAL INFECTIONS

Secondary bacterial infections with standard pathogens, *Mycobacterium tuberculosis*, atypical mycobacteria, and unusual organisms such as *Rhodococcus* and *Bartonella* spp. are a significant cause of morbidity in patients with HIV infection. Patients with HIV infection are particularly prone to infection with encapsulated bacteria. This similarity to patients with immunoglobulin deficiencies may reflect the defects in antigen-specific B-cell activation that have been reported in patients with HIV infection.²¹ The majority of bacterial pneumonias seen in this setting are due to *Streptococcus pneumoniae* and *H. influenzae*. Patients with AIDS have a sixfold increase in the incidence of *S. pneumoniae* bacteremia. These observations emphasize the importance of pneumococcal

vaccination as a prophylaxis strategy in this group.²² In addition, patients with AIDS have a high incidence of bacterial sinusitis, catheter-related sepsis, and pyomyositis. The standard enteric pathogens *Salmonella* spp., *Shigella* spp., and *Campylobacter* spp. are a common cause of dysenteric illness in patients with AIDS and, unlike the non-AIDS population, they are frequently associated with bacteremia.

The re-emergence of *Mycobacterium tuberculosis* as a significant public health problem and the identification of cases of tuberculosis in which the organism is resistant to two or more first-line drugs (multidrug-resistant tuberculosis) have both been a result of the HIV epidemic. In the USA, approximately 5% of patients with HIV infection have active tuberculosis. Worldwide, approximately one-third of all AIDS-related deaths are associated with tuberculosis. Given the inherent pathogenic potential of *M. tuberculosis*, active tuberculosis may be a relatively early manifestation of HIV infection and occur at CD4 T-cell counts >200 cells/mm³.²³ Untreated tuberculosis can accelerate the course of HIV infection and treatment of tuberculosis can lead to decreases in plasma levels of HIV. In patients with early HIV infection, the clinical picture will be similar to that of classic pulmonary reactivation. In more advanced patients, the clinical picture is more likely to be that of disseminated disease. Overall 60–80% of patients will present with pulmonary disease and 30–40% will have extrapulmonary disease. Given the high probability of reactivation, it is recommended that all patients with HIV infection and a positive purified protein derivative (defined as > 5 mm at 48–72 hours) or close contact with active tuberculosis receive antimicrobial therapy. This generally consists of 9 months of isoniazid.

Infections with atypical mycobacteria are seen with an increased frequency in patients with HIV infection.²⁴ Infections with at least 12 different mycobacteria have been reported. The most common of these are *M. avium* and *M. intracellulare*, referred to together as the *Mycobacterium avium* complex (MAC). Infections with MAC are predominantly seen in the USA. They are rare in developing countries. One reason for this may be the observation that infection with MAC is less common in patients with prior tuberculosis. MAC infection is a late complication of HIV infection and typically occurs in patients with CD4 T-cell counts less than 50 cells/mm³. The average CD4 T-cell count at diagnosis is 10 cells/mm³. The most common clinical presentation is disseminated disease with fever, weight loss, and night sweats.

Table 31.3 Secondary infections seen in patients with human immunodeficiency virus (HIV) infection

CD4 count	Etiologic agents	Clinical manifestations
Any CD4 count	Human papillomavirus Herpes simplex Herpes zoster Hepatitis B Hepatitis C Hepatitis D <i>Rochalimaea henselae</i> Encapsulated bacteria <i>Candida</i> spp. <i>Coccidioides immitis</i>	Condyloma acuminata Recurrent ulcers Shingles Persistent antigenemia Chronic hepatitis Chronic hepatitis Bacillary angiomatosis Sinusitis Oral thrush; vaginitis Pneumonia
≤500	Epstein–Barr virus Human herpesvirus 8 Human papillomavirus <i>Mycobacterium tuberculosis</i>	Oral hairy leukoplakia; lymphoma Kaposi sarcoma; lymphoma Cervical or anorectal dysplasia Pneumonia
≤200	<i>Pneumocystis jiroveci</i> <i>Toxoplasma gondii</i> Cryptosporidia/microsporidia <i>Isospora</i> Encapsulated bacteria <i>Shigella</i> , <i>Salmonella</i> , <i>Campylobacter</i> <i>Treponema pallidum</i> <i>Mycobacterium tuberculosis</i>	Pneumonia, disseminated infection Encephalitis; choroiditis Gastroenteritis; diarrhea Diarrhea Pneumonia; sinusitis Dysentery; bacteremia Secondary and neurosyphilis Pneumonia; disseminated disease
≤100	Herpes simplex Herpes zoster Cytomegalovirus JC virus <i>Candida</i> spp. <i>Cryptococcus neoformans</i> <i>Histoplasma capsulatum</i> <i>Penicillium marneffei</i> <i>Mycobacterium avium-intracellulare</i>	Esophagitis Cutaneous dissemination Retinitis; colitis; neuropathy Progressive multifocal leukoencephalopathy Esophagitis Meningitis; pneumonia; dissemination Disseminated disease Disseminated disease Disseminated disease

Eighty-five percent of patients are mycobacteremic and liver and bone marrow involvement are common. Approximately 25% of patients with MAC infection will have an abnormal chest X-ray. The median survival following a diagnosis of MAC is in the range of 6–10 months. This may be more reflective of the late stage of underlying illness rather than the pathogenic contributions of MAC. Primary prophylaxis for MAC infection with azithromycin or clarithromycin is recommended for all patients with HIV infection and fewer than 50 CD4 T cells/mm³.²²

The problem of syphilis has several unique features in patients with AIDS. While the majority of infections with *Treponema pallidum* are typical, there is an increased incidence of neurosyphilis, lues maligna, and nephrotic syndrome. In addition, due to the abnormalities of B-cell activation and regulation in patients with AIDS, serologic testing for syphilis may be challenging. Some patients may exhibit a false-positive rapid plasma reagin due to polyclonal B-cell activation, while others may exhibit a false-negative fluorescent treponemal antigen test due to defects in antigen-specific B-cell activation. Despite these problems, one is usually able to make a diagnosis. Syphilis is a treatable infection and should be high on the differential diagnosis when dealing with patients with HIV infection.

Two additional bacterial pathogens worthy of note in the setting of HIV infection are *Rhodococcus equi* and *Bartonella* spp. *R. equi* is a Gram-positive, pleomorphic acid-fast nonspore-forming bacillus that can cause pulmonary and/or disseminated disease in patients with HIV infection. *Bartonella* spp are fastidious, Gram-negative, *Rickettsia*-like organisms that can cause a variety of clinical syndromes. These infections are usually seen in patients with fewer than 100 CD4 T cells/mm³. The clinical manifestations of *Bartonella* infections include bacillary angiomatosis, peliosis hepatitis, cat-scratch disease, and trench fever. Bacillary angiomatosis and peliosis hepatitis are usually due to *B. henselae*. It is characterized by vascular proliferation that leads to a variety of skin lesions that often resemble the skin lesions of Kaposi's sarcoma. Peliosis hepatitis is a condition in which the liver contains multiple, cystic, blood-filled spaces. Cat-scratch disease usually begins with a papule at the site of inoculation followed in several weeks by regional adenopathy and malaise. Trench fever is due to *B. quintana*, an organism typically transmitted by lice. Diagnosis of *Bartonella* infection can be made through modified conventional bacteriologic culture methods, coculture with endothelial cells, serologic

Fig. 31.3 Magnetic resonance imaging scan of a human immunodeficiency virus (HIV)-infected patient with cerebral toxoplasmosis.

(A) T₁-weighted image showing contrast-enhancing lesions in the parietal and occipital lobes. **(B)** T₂-weighted image showing edema surrounding the two lesions seen on T₁, as well as additional areas of edema in the contralateral frontal and parietal lobes.

or immunocytochemical means, or DNA amplification, or all of these methods. Prolonged treatment with erythromycin or doxycycline is usually effective.

FUNGAL INFECTIONS

Fungal infections account for a significant degree of morbidity and mortality in patients with AIDS. *Pneumocystis jirovecii* (previously *carinii*) pneumonia (PCP) was once the hallmark of AIDS. Its incidence has decreased dramatically with the widespread use of combination antiretroviral therapy and primary prophylaxis with sulfamethoxazole/trimethoprim in patients with CD4 T-cell counts under 200 cells/mm³. Overall, 95% of patients with PCP have CD4 T-cell counts under 200 cells/mm³ and 79% of patients have CD4 T-cell counts under 100 cells/mm³. The risk of PCP is highest in patients with a prior bout of PCP. In contrast to other immunocompromised hosts, patients with AIDS-associated PCP generally present with a protracted indolent illness characterized by fever, shortness of breath, scant cough, and minimal changes on chest X-ray. Extrapulmonary disease with *P. jirovecii* may present as choroiditis, vasculitis, lymphadenopathy, and/or visceral disease.

Mucocutaneous infections with *Candida* spp. can be seen prior to a diagnosis of AIDS and in that setting are associated with an increased risk of progressing to AIDS. In contrast to other immunocompromised conditions, patients with AIDS rarely develop invasive disease with *Candida*. Exceptions to this are the patient with an indwelling catheter receiving broad-spectrum antibiotics and the patient with drug-induced neutropenia. While the majority of cases of *Candida* infection involve the mucosal surfaces of the oropharynx and/or the vagina, in patients with advanced HIV infection one may also see involvement of the tracheobronchial tree and/or the esophagus. These latter two conditions are sufficiently indicative of advanced immunodeficiency to be included in the list of AIDS-defining illnesses.

Cryptococcus neoformans is the leading cause of meningitis in patients with HIV infection.²⁵ This is usually a late manifestation of HIV infection

and generally occurs in patients with fewer than 100 CD4 T cells/mm³. Cryptococcal meningitis can be indolent in onset with patients complaining of fever, headache, and nausea for weeks to months prior to diagnosis. In addition to meningitis, patients with AIDS and cryptococcal disease may present with CNS mass lesions due to cryptococcomas, pulmonary disease with focal or diffuse interstitial infiltrates on chest X-ray, or unexplained fever with positive blood cultures. Overall 50% of patients with cryptococcal disease have fungemia and over 90% have detectable levels of cryptococcal antigen in their serum.

Histoplasmosis and coccidioidomycosis are also seen with an increased frequency in patients with AIDS. Histoplasmosis is almost exclusively seen in patients from the Mississippi or Ohio river valleys, Puerto Rico, Dominican Republic, or South America. It commonly presents as disseminated disease with fever, weight loss, and hepatosplenomegaly.²⁶ An interstitial pattern is present on chest X-ray in about half of the patients. The bone marrow is involved in one-third of cases and one may see mucocutaneous lesions. Disseminated histoplasmosis is generally a late manifestation of HIV infection, occurring in patients with under 100 CD4 T cells/mm³. In contrast, coccidioidomycosis may occur in patients with relatively intact immune systems, although the majority of cases have been in patients with CD4 T-cell counts under 250 cells/mm³. It is also seen in a geographically limited distribution, with the highest incidence in patients who have been in the southwest USA. The most common manifestations of coccidioidomycosis are fever, weight loss, and cough with diffuse reticulonodular infiltrates on chest X-ray. As in other settings with HIV-infected individuals, serologic testing may be unreliable. Up to 25% of patients with coccidioidomycosis and HIV infection may not have a positive serology.

Penicillium marneffei is a common opportunistic infection in Southeast Asia. It is the third most common opportunistic infection in Thailand, behind tuberculosis and cryptococcosis.²⁷ It is most common during the rainy season. Clinical features include fever, generalized lymphadenopathy, hepatosplenomegaly, anemia, thrombocytopenia, and papular skin lesions with central umbilication. Invasive aspergillosis is not an AIDS-defining

illness and is rarely seen in patients with HIV infection outside the setting of neutropenia or corticosteroid treatment. An unusual feature of respiratory tract involvement with aspergillosis in patients with AIDS is that of a pseudomembranous tracheobronchitis.

VIRAL INFECTIONS

Reactivation syndromes of human herpes viruses are among the most common problems in patients with HIV infection and AIDS. Nearly all patients with untreated AIDS actively shed CMV. Once the CD4 count drops below 100 cells/mm³, patients begin to develop clinical problems as a result of CMV reactivation.²⁸ The most common serious problem is CMV retinitis, which can lead to permanent blindness. In addition, CMV can cause esophagitis, colitis, pneumonia, ascending myelitis, and peripheral polyneuropathy. Herpes simplex reactivation can result in painful orolabial, genital, digital, and/or perianal ulceration that increases in severity as immunologic function declines. It can also cause an erosive esophagitis. Reactivation of varicella-zoster virus commonly results in dermatomal zoster (shingles); however, patients with advanced HIV infection may develop a form of cutaneous dissemination resembling a mild case of chickenpox. This can be a recurrent problem and patients with HIV infection who experience about of shingles may have one or more relapses.²⁹ Despite extensive cutaneous involvement, visceral dissemination of varicella-zoster virus is almost never seen. Epstein-Barr virus (EBV), the etiologic agent of one form of infectious mononucleosis, is also shed by the majority of patients with untreated HIV infection. It is associated with the development of oral hairy leukoplakia, a white frond-like lesion seen on the lateral aspect of the tongue. This condition is generally benign and rarely needs treatment. In addition up to 50% of the lymphomas seen in AIDS patients have been found to be contain EBV genome.³⁰ Human herpesvirus 8 (HHV-8) is one of the newest members of this family. It has been associated with the development of Kaposi's sarcoma, multicentric Castleman's disease, and primary effusion lymphomas in the setting of HIV infection.³¹ The prevalence of HHV-8 in HIV-infected men is 30–35%, while its prevalence in HIV-infected women is approximately 4%.³²

Approximately one-third of the deaths of patients with HIV infection are related in some way to liver disease. This is predominantly a reflection of the problems encountered in the setting of co-infection with HIV and hepatitis virus(es) coupled with drug-induced hepatic injury in association with antiretroviral therapy. Over 95% of HIV-infected individuals have evidence of infection with hepatitis B and, in the USA, > 20% of patients are chronically infected with hepatitis C. Co-infection with hepatitis D, E, and/or G viruses is also common. Patients with AIDS do not appear to have an increased risk of inflammatory liver disease in association with hepatitis B infection. This is presumably due to their underlying immunodeficiency. In contrast, hepatitis C infection is more severe in patients with HIV infection, with approximately 10-fold higher levels of hepatitis C virus in the blood and a higher incidence of liver failure.

Among the other viruses that cause problems in patients with HIV infection and AIDS are molluscum contagiosum virus, human papillomavirus (HPV), and JC virus. Diffuse, flesh-colored, umbilicated skin lesions due to molluscum contagiosum may be seen in patients with advanced HIV infection. They frequently regress with effective antiretroviral therapy. Human papillomavirus is approximately twice as common in patients with HIV infection (81%) as in the general population.³³

This virus has been associated with epidermal dysplasia. Compared to the general population, women with HIV infection have a 10-fold increase in the incidence of abnormal Papanicolaou smears and an increased incidence of intraepithelial neoplasia. Given the potential of these lesions to progress to invasive cancer, women with HIV infection should undergo periodic Papanicolaou smear examinations. Another manifestation of HPV infection, condyloma acuminata, may present with more severe and widely distributed lesions in patients with advanced HIV infection.

JC virus is a human papova virus. It is the etiologic agent of progressive multifocal leukoencephalopathy (PML). This demyelinating disease of the nervous system is seen in 4% of HIV-infected individuals and is a late manifestation of HIV infection and AIDS. Patients typically present with multiple neurologic deficits with or without a change in mental status. Although marked recoveries have been reported following the initiation of antiretroviral therapy,³⁴ PML remains one of the few opportunistic infections continuing to occur with some frequency in patients with HIV infection.

INFECTIONS IN PATIENTS RECEIVING IMMUNOSUPPRESSIVE DRUGS

At pharmacologic doses, glucocorticosteroids have both anti-inflammatory and immunosuppressive properties, which result from the effects these agents have on the distribution and function of lymphocytes, monocytes, and neutrophils.³⁵ The major anti-inflammatory actions of glucocorticosteroids are in large part due to their suppressive effects on neutrophil function. Glucocorticosteroids inhibit neutrophil migration to inflammatory sites, reduce neutrophil adherence to vascular endothelium, reduce the bactericidal activity of neutrophils, and stabilize lysosomal membranes (Chapter 87). The latter two effects are only observed at high glucocorticosteroid concentrations and may not be of clinical importance. Glucocorticosteroid therapy produces a neutrophilic leukocytosis by accelerating release of mature neutrophils from the bone marrow, and by reducing the egress of neutrophils from the circulation into inflammatory sites.³⁶ The total white blood cell count may exceed 20 000/mm³, but band forms and metamyelocytes almost never increase beyond 6% of the total white blood cell count. An excess of these immature neutrophil forms is suggestive of a superimposed infectious process.

The mononuclear phagocytic system is also affected by glucocorticosteroid therapy. In contrast to the effect on neutrophils, glucocorticosteroid administration produces a peripheral blood monocytopenia. Glucocorticosteroids impair a number of monocyte functions important to host defense, including chemotaxis, bactericidal activity, clearance of antibody-coated red blood cells, and production of proinflammatory cytokines.

Glucocorticosteroids cause profound changes in lymphocyte function and induce a redistribution of lymphocytes out of the circulation. This redistribution predominantly involves T lymphocytes, with CD4 cells affected more than CD8 T cells. Glucocorticosteroids also inhibit T-lymphocyte activation, leading to decreased proliferation and lymphokine production.³⁷ At high doses, glucocorticosteroids are able to inhibit immunoglobulin production by B cells.³⁸

In view of the broad immunosuppressive and anti-inflammatory effects of glucocorticosteroids, it is not surprising that treatment with these agents is associated with an increased frequency of infections. The infections that occur in glucocorticosteroid-treated patients are those associated with impaired phagocyte function (i.e., infections caused by staphylococci, enteric Gram-negative bacteria, *Aspergillus* spp., *Nocardia* spp.) and, to a lesser extent, those associated with suppressed cell-mediated immunity (viral, fungal, *P. jiroveci*, *Listeria* spp., and mycobacterial infections). Although there is no doubt that glucocorticoid therapy results in an increased susceptibility to infection, the exact magnitude of this problem is difficult to quantify. Experience in patients with rheumatoid arthritis, systemic lupus erythematosus, and other autoimmune diseases suggests that the incidence of infectious complications increases with doses equivalent to 20–40 mg/day of prednisone administered for longer than 4–6 weeks.³⁹ It is important to note that serious infections rarely occur in patients treated with alternate-day glucocorticosteroid therapy and this form of therapy should be employed whenever possible.³⁷

Cytotoxic drugs such as cyclophosphamide and methotrexate disrupt host defense through their inhibitory effects on cell proliferation (Chapter 90). Cyclophosphamide is a potent immunosuppressant that interferes with B- and T-cell responses. In the treatment of rheumatic diseases, cyclophosphamide is usually given in combination with glucocorticosteroids. This combination is associated with the same types of bacterial and opportunistic infections that occur with high-dose glucocorticosteroid therapy.⁴⁰ Pneumonia due to *P. jiroveci* is the most common opportunistic infection seen in patients receiving cyclophosphamide plus daily glucocorticosteroid therapy. When cyclophosphamide is given alone or with alternate-day glucocorticosteroid therapy, the incidence of infectious complications is markedly reduced.

Low-dose methotrexate (10–20 mg once a week) is increasingly being used as a treatment for rheumatoid arthritis. Initial studies suggested that this methotrexate regimen was not associated with the occurrence of opportunistic infections. However, with widespread use of this regimen, opportunistic infections due to *P. jiroveci* and *Cryptococcus neoformans* have been reported in patients receiving low-dose weekly methotrexate therapy in the absence of concomitant glucocorticosteroid therapy or neutropenia.⁴¹

Cyclosporine A and azathioprine are potent immunosuppressive agents that are predominantly used to suppress rejection of transplanted organs. Treatment with these agents is associated with a variety of opportunistic infections that are described below.

In recent years, specific inhibitors of the proinflammatory cytokine, tumor necrosis factor (TNF), have become a part of treatment regimens for certain autoimmune diseases such as rheumatoid arthritis and inflammatory bowel disease. In pre-marketing trials, the use of these agents was not associated with a discernible increase in infections. However, post-marketing reporting has provided increasing evidence that treatment with TNF inhibitors (especially infliximab) may be associated with an increased incidence of tuberculosis and other infections.⁴²

■ INFECTIONS IN SOLID-ORGAN TRANSPLANT RECIPIENTS ■

During the past two decades the transplantation of solid organs has gone from being an experimental procedure to an accepted therapeutic modality. Advances in surgical techniques and improved immunosuppressive

CLINICAL PEARLS

INFECTIONS IN SOLID-ORGAN TRANSPLANT RECIPIENTS

- >> Most infections occur in the first 6 months following transplantation
- >> In the first month, most infections are nosocomial or are related to surgical procedures or pre-existing infection in the donor or recipient
- >> Infections between 1 and 6 months following transplantation are commonly secondary to the use of immunosuppressive drugs, with a predominance of cytomegalovirus infection
- >> Infections after 6 months are usually due either to chronic viral infection, acquired earlier, or to chronic allograft dysfunction, necessitating repeated courses of high-dose immunosuppression

regimens have led to 1-year survival rates in excess of 70% for recipients of kidney, liver, and heart transplants (Chapter 80). Despite these advances, infection continues to be a major cause of morbidity and mortality in patients undergoing solid-organ transplantation. The types of infections along with their clinical manifestations and severity are determined by the interaction of several factors, including the specific organ transplanted, exposure to potential pathogens, and the level of immunosuppression.

TIME COURSE OF INFECTIONS AFTER TRANSPLANTATION

The majority of infectious complications occur in the first 6 months following transplantation. In the early post-transplant period (first 4 weeks), most clinically overt infections are due to nosocomial bacterial or fungal pathogens and are directly related to the surgical procedure, invasive monitoring with intravascular devices, postoperative pulmonary complications, or pre-existing infection in the organ donor or recipient.⁴³

From 1 to 6 months post-transplant, infections related to the use of immunosuppressive agents predominate. A number of opportunistic infections can occur during this period (Table 31.4). Because the diversity of possible pathogens is so great, identifying the specific causative agent is essential to select appropriate and effective therapy. CMV is the dominant pathogen causing disease during this period. The majority of patients undergoing solid-organ transplantation will show evidence of CMV infection, as determined by serological rise in titer or virus isolation from the blood, urine, or throat.⁴³ However, not all patients with infection will develop clinical disease. There are two major determinants of whether CMV infection will progress to clinical disease. The first is the prior experience of the donor and recipient with CMV, which determines whether the infection is primary or due to reactivation of latent virus. The transplantation of an organ from a CMV-seropositive donor into a seronegative recipient will result in primary CMV infection. Primary infection is more likely to be associated with clinical disease than is CMV reactivation.⁴³ The second determinant of whether CMV infection will result in clinical disease is the type and intensity of immunosuppression.

Table 31.4 Time course for opportunistic infections after solid-organ transplantation

Months after transplantation	Major risk factors	Major pathogens
1	Surgical procedure, intravascular catheters; pre-existing infection in donor or recipient	Conventional nosocomial bacterial and fungal pathogens
2–6	Immunosuppressive therapy	Cytomegalovirus, <i>Cryptococcus neoformans</i> , <i>Listeria monocytogenes</i> , <i>Pneumocystis jiroveci</i> , <i>Toxoplasma gondii</i> , <i>Aspergillus</i> spp., <i>Candida</i> , <i>M. tuberculosis</i> , <i>Nocardia</i> spp., hepatitis B or C virus, Epstein–Barr virus
>6	Immunosuppressive therapy Chronic viral infection	<i>Cryptococcus neoformans</i> , <i>Listeria monocytogenes</i> , <i>Nocardia</i> spp., <i>Aspergillus</i> and non- <i>Aspergillus</i> molds Late complications of chronic hepatitis, Epstein–Barr virus Cytomegalovirus retinitis

Treatment with glucocorticosteroids alone is associated with a very low incidence of CMV disease. In fact, CMV disease was essentially unknown in transplant patients prior the introduction of agents such as cyclophosphamide, azathioprine, and cyclosporine A into anti-rejection regimens.⁴³ Of all the immunosuppressive agents used, polyclonal or monoclonal anti-T-cell antibodies are the most potent inducers of CMV disease.⁴⁴

The most common type of CMV disease in the transplant recipient is a mononucleosis-like syndrome characterized by prolonged fever, leukopenia, arthralgias, and abnormal liver function tests. Splenomegaly and lymphadenopathy are usually not present. A more serious manifestation of CMV infection is interstitial pneumonitis, which can be severe and life-threatening. The clinical manifestations of CMV pneumonitis are nonspecific, and diagnosis by bronchoalveolar lavage or lung biopsy is required. Infection of the gastrointestinal tract with CMV can lead to an ulcerative disease with associated bleeding and perforation. Although chemical hepatitis is frequently seen in patients with the mononucleosis syndrome, severe CMV hepatitis is unusual. The exception is in recipients of liver transplants where CMV hepatitis may be severe and occasionally lead to hepatic failure.⁴⁵ It is important to note that CMV disease may be complicated by co-infection with other opportunistic pathogens, most notably *P. jiroveci*. The potentially severe sequelae from CMV disease in recipients of solid organ transplants have led to the widespread use of antiviral prophylaxis or pre-emptive therapy to prevent CMV disease.

Infectious complications that occur more than 6 months post-transplant are usually due to one of two possibly interrelated factors: (1) the effects of chronic viral infection acquired earlier and (2) chronic allograft dysfunction which necessitates repeated courses of high-dose immunosuppressive therapy. Examples of chronic viral infections that can become clinically manifest during this period include CMV chorioretinitis, chronic hepatitis with or without cirrhosis due to hepatitis B or C viruses, and EBV-associated lymphoproliferative disease. Patients who experience chronic allograft rejections and require high doses of immunosuppressive agents are at risk for infections with opportunistic pathogens

CLINICAL PEARLS

INFECTIONS IN BONE MARROW TRANSPLANT RECIPIENTS

- >> Infections 2–4 weeks post-transplantation are usually due to profound neutropenia and damage to mucosal surfaces
- >> Between the period of engraftment and weeks 15–20 post-transplant, opportunistic infections predominate and are commonly associated with the development of acute graft-versus-host disease and its treatment
- >> Serious infections occurring 4–6 months following transplantation are seen predominantly in patients with chronic graft-versus-host disease

such as *P. jiroveci*, *C. neoformans*, *Listeria monocytogenes*, *Nocardia* species, *Aspergillus* and non-*Aspergillus* molds.

INFECTIONS IN BONE MARROW TRANSPLANT RECIPIENTS

Allogeneic bone marrow transplantation has become an accepted mode of therapy for hematological malignancies, immunodeficiency disorders, and aplastic anemia (Chapters 82 and 83). Marrow graft recipients undergo treatment with chemoradiotherapy which virtually ablates the existing hematological and immunologic marrow elements and provides a state of immunodeficiency that permits engraftment of the donor marrow. This state of profound immunosuppression places the recipient at high risk for a variety of infectious diseases. Significant abnormalities of T- and B-lymphocyte function that persist following recovery of neutrophil counts place the patient at continued risk for infection with viral and fungal pathogens.

TIME COURSE OF INFECTIONS AFTER TRANSPLANTATION

From an infectious diseases viewpoint, the post-transplant period can be divided into three phases that correlate with the initial ablation and ensuing recovery of hematopoietic and immunologic function. During the first weeks post-transplantation the predominant risk factors for infection are profound neutropenia and damage to mucosal surfaces that results from pre-transplant ablative radiation and chemotherapy. These host defense defects predispose the patient to the same types of bacterial and fungal infections seen in cancer patients undergoing induction chemotherapy. As would be expected, the prevalence of invasive fungal infections increases with the duration of neutropenia. Viral infections, other than herpes simplex virus, are uncommon during this period. Herpes simplex viral infections occur at a time of maximal mucosal damage by radiation and chemotherapy and may cause severe stomatitis and esophagitis. Aciclovir is effective for treatment and prophylaxis of this infection.

Between the period of engraftment and weeks 15–20 post-transplant, infections with opportunistic viral, fungal, and protozoal pathogens (i.e., CMV and *P. jirovecii*) predominate. The major predisposing factors for these infections are the immunosuppressive effect of acute graft-versus-host disease (GvHD) and its treatment. CMV is a major pathogen during this period. CMV infection occurs in 30–40% of seronegative transplant patients who receive unscreened blood products post-transplant and CMV reactivation occurs in the majority of patients who were CMV-seropositive prior to transplantation.⁴⁶ The risk of CMV infection and disease is increased in patients with acute GvHD. Manifestations of CMV infection are similar to those seen in solid-organ transplant patients, but tend to be more severe. Pneumonia is the most serious manifestation of CMV infection and, prior to the use of pre-emptive therapy, occurred in approximately one-third of marrow transplant patients. Risk factors for the development of CMV pneumonia include older age and acute GvHD.⁴⁶ In the marrow transplant recipient, the technique of centrifugation culture of bronchoalveolar lavage fluid for CMV has been shown to be both sensitive and specific for diagnosing CMV pneumonia, making open-lung biopsy unnecessary in most cases.⁴⁷ In the past, the fatality rate for CMV pneumonia was in excess of 80%. Even with the use of ganciclovir and intravenous immunoglobulin, mortality rates from CMV pneumonia are 20–50%. Thus, current strategies focus on preventing CMV disease by using pre-emptive treatment with ganciclovir or foscarnet.⁴⁸ Nonbacterial, nonfungal interstitial pneumonia that is not due to CMV infection can also occur in marrow transplant recipients. Most cases occur between days 30 and 100 post-transplant. Reported infectious causes of this syndrome include *P. jirovecii*, adenovirus, parainfluenza virus, and respiratory syncytial virus. Approximately one-third of interstitial pneumonia cases are idiopathic and may be due to toxic effects of radiation and chemotherapy.

Invasive *Aspergillus* infections are also seen during this post-transplant period. The main risk factors for the occurrence of invasive aspergillosis after day 40 of transplant are severe GvHD and glucocorticosteroid use.⁴⁹

Serious infections occurring 4–6 months after transplantation occur predominantly in patients with chronic GvHD.⁵⁰ Following immune reconstitution, marrow transplant recipients exhibit deficient humoral immune responses to both protein and polysaccharide antigens and these abnormalities are more pronounced in patients with chronic GvHD.⁵¹

THERAPEUTIC PRINCIPLES

PREVENTION OF INFECTION IN PATIENTS WITH A DEFECT IN HOST DEFENSES

- >> Use of prophylactic antibiotics in patients at high risk for a specific type of infection
- >> Immunization to prevent specific bacterial and viral infections
 - Active immunization, especially in patients who should be capable of mounting an effective response (e.g., before elective splenectomy or before elective initiation of immunosuppressive therapy)
 - Passive immunization through administration of high-titer pooled immunoglobulin to patients exposed to or at high risk of specific viral infections

Clinically, the most common infections are bacterial and involve the respiratory tract and skin, or present as sepsis without apparent source. The most common organisms isolated are Gram-positive bacteria, particularly *Streptococcus pneumoniae*.⁵⁰ Thus, patients with chronic GvHD exhibit a humoral immune defect similar to that seen in patients with Hodgkin's disease who have received combined radiation and chemotherapy (see above). In patients receiving immunosuppressive therapy for chronic GvHD, invasive infections with *Aspergillus* and non-*Aspergillus* molds can also occur during this period.⁴⁹

Herpes virus infections are also seen during the late post-transplant period. Approximately 40% of marrow transplant recipients will develop varicella-zoster virus infections, usually in the form of herpes zoster.⁵² The median time to onset is 5 months after transplantation, with most cases occurring in the first year. Infections with EBV can also occur during this period and EBV-associated lymphoproliferative disease has been observed after marrow transplantation.³⁰

IMPROVING HOST DEFENSE

In the patient who exhibits a defect in host defense, prevention of infection is a desirable goal, albeit difficult to attain. One of the most effective means of partially achieving this goal is through the use of prophylactic antibiotics in those settings where patients are at increased risk for a specific type of infection. An example of this is the use of trimethoprim/sulfamethoxazole for prophylaxis against PCP in patients with HIV infection and CD4 counts less than 200 cells/mm³. Immunization against bacterial and viral pathogens has also played a major role in the prevention of certain infectious diseases. Unfortunately, active immunization is often unsuccessful in immunocompromised hosts, as they are unable to generate a protective cellular or humoral response to vaccination. On the other hand, passive immunization through the administration of pooled immune globulin may be effective in preventing certain infections in the immunocompromised host. Examples include the use of varicella-zoster immune globulin in immunocompromised children exposed to varicella and the administration of CMV hyperimmune globulin to CMV-seronegative renal allograft recipients.⁵³ In both of these situations the use of hyperimmune globulin is associated with a decrease in the severity of disease.

In the near future our increasing understanding of cytokines and their immunologic effects will likely lead to improved forms of immunotherapy for a variety of immunodeficiency diseases. Over the next decade, these powerful biological agents will play an important role in restoring immunologic function in the compromised host and decreasing the incidence of infectious diseases.

Development of the fetal and neonatal immune system

David B. Lewis

32

The fetus and neonate are more vulnerable than older children and adults to severe infection with a variety of pathogens, including pyogenic bacteria, fungi, viruses, and intracellular protozoa.¹ This indicates that there are substantial limitations in innate and adaptive immunity in prenatal and early postnatal life. The results of hematopoietic stem-cell transplantation also provide compelling evidence for impairment of neonatal T-cell immunity. For example, allogeneic hematopoietic cell transplantation with cord blood results in a significantly lower risk of acute graft-versus-host disease – a disease that is mainly mediated by donor-derived naïve T cells – compared to bone marrow and peripheral blood transplants containing adult T cells.² These clinical observations have made defining the physiologic immaturity of the human fetal and neonatal immune system of great interest.

■ DENDRITIC CELLS AND ANTIGEN PRESENTATION ■

Activated conventional dendritic cells (cDCs) participate in antigen presentation to T cells and B cells and produce critical cytokines, e.g., interleukin (IL)-12p70 and IL-15, that provide early innate immune protection and also influence the outcome of the later adaptive immune response (Fig. 32.1). Plasmacytoid dendritic cells (pDCs) are a distinct DC population that is mainly found in lymphoid tissue and the circulation and that interacts with and enhances the activation of cDCs. Activated pDCs are an important source of interferon (IFN)- α and IFN- β , which provide early innate antiviral immunity, and also enhance the later adaptive immune response, including differentiation of Th1 lymphocytes. DCs are activated by a variety of stimuli, including the recognition of conserved structures of microbial pathogens by Toll-like receptors (TLRs) (Chapter 3).

DCS IN TISSUES

The colonization of cDCs in extra-lymphoid tissues appears to be developmentally regulated, and independent of exposure to inflammatory mediators. Immature cDC lineage cells have been identified in the interstitium of solid

CLINICAL RELEVANCE

EXAMPLES OF INFECTIONS MORE FREQUENT OR SEVERE IN THE FETUS AND NEONATE THAN IN OLDER CHILDREN AND ADULTS

- >> Bacteremia and meningitis due to pyogenic bacteria, e.g., group B streptococcus – higher rate in neonatal period than any other age group
- >> Primary herpes simplex virus infection – approximately 25–30% mortality in the neonate even with current antiviral therapy, e.g., aciclovir
- >> Enteroviral infection – severe infection, e.g., hepatic necrosis with disseminated intravascular coagulation, which is unusual outside the neonatal period except in cases of severe T-cell immunodeficiency such as severe combined immunodeficiency (SCID)
- >> Toxoplasmosis – congenital infection typically disseminates to the retina; disseminated infection is unusual in postnatally acquired infection
- >> *Mycobacterium tuberculosis* acquired congenitally or perinatally has a high risk of progressing to miliary disease and meningitis
- >> Mucocutaneous candidiasis in the otherwise healthy neonate is more frequent compared to older children and adults

organs, including the kidney, heart, pancreas, and lung, but not the brain, by 12 weeks of gestation, and the numbers of these cells increase progressively by 21 weeks.³ Epidermal Langerhans cells, a cDC population unique to the dermis, are found in the skin even earlier, at 7 weeks' gestation.

CIRCULATING AND MONOCYTE-DERIVED DCs

Most studies of the developmental immunology of human DCs have analyzed circulating DCs, the main caveat being whether these results also apply to the phenotype and function of tissue DCs. Circulating

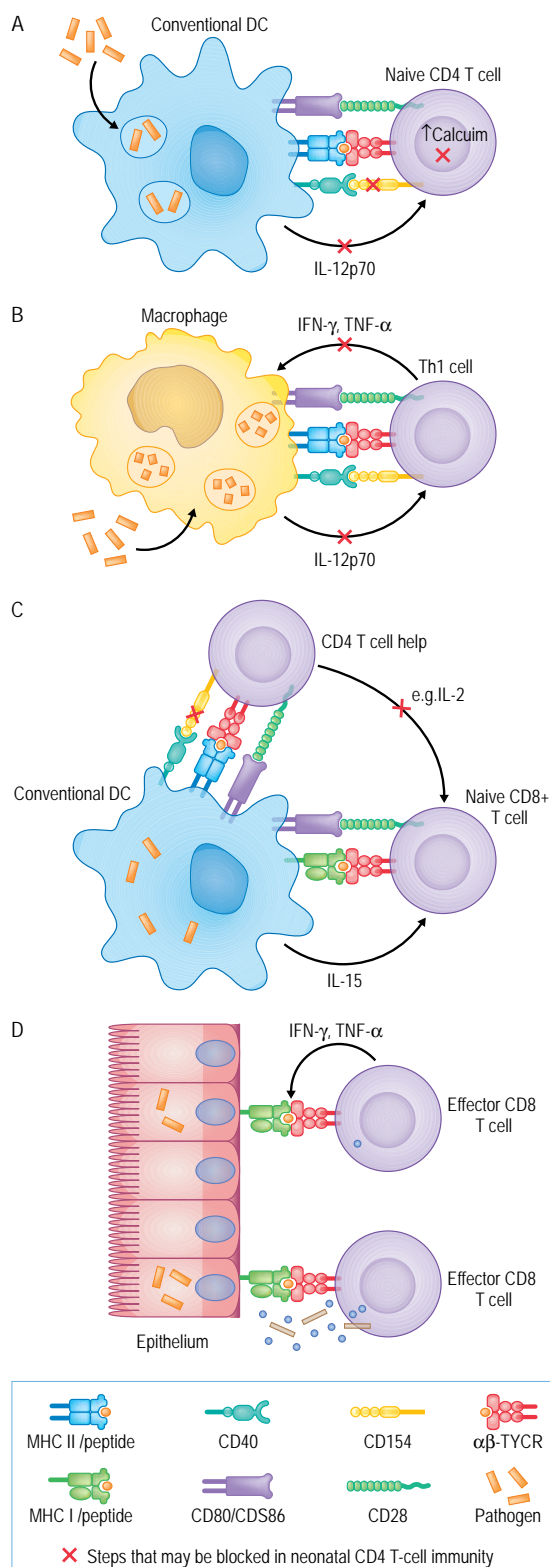

Fig. 32.1 T-cell activation and differentiation in response to antigen. Steps that may be blocked in neonatal CD4 T cells are indicated as red Xs. **(A)** Th1 generation from naive CD4 T cells requires that conventional dendritic cells (cDCs) present antigenic peptides bound to major histocompatibility complex (MHC) class II and co-stimulatory molecules, such as CD80 and CD86. T-cell activation results in calcium-dependent increases in CD154 on the CD4 T-cell surface. The CD154–CD40 interaction enhances cDC production of interleukin (IL)-12p70, which promotes Th1 differentiation. **(B)** Differentiated Th1 cells help kill intracellular pathogens, such as *Mycobacterium tuberculosis*, that hide in the intracellular microvesicular compartments of macrophages. Pathogen-derived peptides bound to MHC class II displayed on the infected cell surface engage the $\alpha\beta$ -T-cell receptor (TCR) of the Th1 cell, triggering its secretion of interferon (IFN)- γ and tumor necrosis factor (TNF)- α . These cytokines bind to specific surface receptors on the infected cell and increase its microbicidal activity. **(C)** The generation of CD8 T-cell effectors from naive CD8 T cells requires $\alpha\beta$ -TCR engagement by cognate peptide/MHC class I complexes on the cDC, CD80/CD86-CD28 co-stimulation, cDC-derived IL-15, and, possibly, cytokines from CD4 T cells. **(D)** CD8 T-cell effectors secrete perforin and granzymes, which kill target cells displaying viral peptide/MHC class I, and IFN- γ and TNF- α , which have antiviral activity and enhance antigen presentation.

cDCs are typically CD11c^{high} and major histocompatibility complex (MHC) class II^{high} but lineage-negative (Lin[−]), i.e., lacking markers for other cell lineages, such as T cells, monocytes, B cells, natural killer (NK) cells, granulocytes, and erythroid cells. Human pDCs are CD11c^{low}Lin[−] and express high levels of CD123 (IL-3 receptor α -chain) and BDCA-4, a pDC-specific cell marker of unknown function. The concentrations of cDCs in cord blood and adult peripheral blood are similar.³ Cord blood cDCs also have a surface phenotype similar to that of adult cDCs. An exception is CD86, which binds to CD28 on T cells, providing a co-stimulatory signal, and which is lower on cord blood cDCs than those of the adult. The concentration of pDCs in cord blood is significantly higher than in adult peripheral blood, and the number of these cells gradually declines after birth.³ The relative predominance of pDCs in the neonatal circulation may reflect the relatively high rate of pDCs colonizing lymphoid tissue, which undergoes rapid expansion at this age.

Circulating neonatal DCs have selective limitations in the TLR-mediated upregulation of expression of molecules involved in T-cell co-stimulation by engagement of CD28 (CD80 and CD86) and other DC–T-cell interactions (MHC class II and CD40) compared to those of the adult.³ For example, cord blood cDCs have reduced expression of CD40 in response to ligands for TLR-2/6 (*Mycoplasma fermentans*), TLR-3 (poly I:C), TLR-4 (lipopolysaccharide (LPS)), and TLR-7 (imiquimod), and reduced CD80 in response to TLR-3 and TLR-4 ligands. In contrast, cDC upregulation of CD40 in response to GU-rich single-stranded RNA, a TLR-8 ligand, is similar,⁴ as is MHC class II and CD86 upregulation after stimulation with TLR3 and TLR-4 ligands. Cord blood and adult peripheral blood pDCs also have similar upregulation of HLA-DR, CD80, and CD86 after stimulation with TLR-9 ligands, i.e., DNA lacking methylated CpG residues (unmethylated CpG DNA).³

Th1 immunity may be particularly limited in the neonate and young infant compared to older individuals because of decreased IL-12p70 production by cDCs, e.g., in response to LPS plus IFN- γ .⁵ However, this limitation may be pathogen-dependent, as decreased IL-12 production by cord blood cDCs is probably comparable to adult cDCs after stimulation with certain Gram-positive and Gram-negative bacteria or meningococcal outer-membrane proteins.¹ Circulating DCs from cord blood can also allogeneically stimulate cord blood T cells *in vitro*,¹ but it is unclear if they are as effective as adult DCs in promoting Th1 differentiation in an allogeneic context.

The production of type I IFNs (IFN- α and IFN- β) by circulating cDCs and pDCs is also reduced in cord blood, and could contribute to the limited ability of the neonate to control pathogens such as herpes simplex virus (HSV) (see below). For example, IFN- α production by cord blood cDCs in response to a TLR-3 ligand and by cord blood pDCs in response to TLR-9 ligands – such as live or inactivated HSV, which has a genome containing unmethylated CpG DNA sequences, or to synthetic unmethylated CpG DNA oligonucleotides – is reduced compared to adult DCs.³ The levels of TLR-9 within the endosomes of adult and cord blood pDCs are similar, suggesting that these decreased responses are due to events downstream of TLR ligand binding.^{3,6}

Several studies have compared the function and phenotype of monocyte-derived dendritic cells (MDDCs) produced by culturing cord blood or adult peripheral blood monocytes *in vitro* with cytokines, such as granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-4, and tumor necrosis factor (TNF)- α . In general, cord blood MDDCs have reduced levels of IL-12p70 expression after stimulation, but it remains unclear if these and other functional and phenotypic differences apply to neonatal and adult DCs of the tissues.

POSTNATAL DC MATURATION

Defining the role of exposure to commensal bacteria in the postnatal maturation of DC function is important, as it provides insight as to how the immune system transitions between interacting with a sterile environment to one in which pathogens versus harmless commensals must be distinguished. Impaired TLR-4 signaling in young (6-week-old) mice results in their cDCs having reduced expression of CD86 and a decreased capacity to produce IL-12 after engagement of the cDC CD40 molecule.⁷ This suggests that cDCs from neonates are functionally immature until their postnatal exposure to bacterial products, such as LPS, and that a lack of such maturation could impair Th1 responses. This idea is consistent with gradual increase during the first 4–6 weeks after birth of the capacity of murine cDCs to produce IL-12p70 and to express adult levels of various surface markers.³

T CELLS

ONTOGENY OF THYMIC DEVELOPMENT

Initial colonization of the fetal thymus by prothymocytes occurs at 8.5 weeks of gestation, with dramatic increases in thymic cellularity during the second and third trimesters. Transient thymic involution, particularly the loss of cortical double-positive (CD4^{hi}CD8^{hi}) thymocytes, may occur at the end of the third trimester due to a prenatal surge in

the circulating levels of glucocorticoids;⁸ this is followed by thymic recovery at 1 month of age.

REPERTOIRE OF $\alpha\beta$ -T-CELL RECEPTORS

The usage of T-cell receptor (TCR) D and J gene segments in the thymus is initially less diverse than subsequently. The complementarity determinant region 3 (CDR3) region of the TCR chain transcripts is also reduced in length and sequence diversity between 8 and 15 weeks of gestation. This is most likely due to decreased activity of terminal deoxynucleotidyl transferase (TdT), which performs N-nucleotide addition during V(D)J recombination. The impact, if any, of these limitations in $\alpha\beta$ -TCR diversity on the ability of the fetus to respond to congenital infection is likely to be subtle and brief, as intrathymic TdT activity, CDR3 length, and V segment diversity during the second trimester are similar to that of postnatal thymic tissue.¹ The TCR repertoire expressed on cord blood T cells has a diversity of TCR usage and CDR3 length similar to that of antigenically naïve T cells in adults and infants, indicating that the functional pre-immune repertoire is fully formed by birth.⁹

TCR excision circles (TREC) are generated during TCR gene rearrangement of thymocytes, and may persist for long periods in T-lineage cells that do not proliferate. TREC levels in cord blood are relatively high compared to adult peripheral blood, as would be expected given the predominance of naïve (CD45RA^{high}CD45RO^{low}) T cells in cord blood. In addition, the cord blood CD8 T-cell compartment is enriched in recent thymic emigrants (RTEs),¹⁰ which also have a higher TREC content than more mature circulating naïve T cells.

FETAL T-CELL DEVELOPMENT AND PHENOTYPE

By 14 weeks of gestation, CD4 and CD8 T cells are found in the fetal circulation, liver, and spleen, and CD4 T cells are detectable in lymph nodes. The percentage of circulating T cells gradually increases during the second and third trimesters of pregnancy through about 6 months of age, followed by a gradual decline to adult levels. The ratio of CD4 to CD8 T cells in the circulation is relatively high during fetal life (about 3.5) and gradually declines with age.

Circulating T cells in the term and preterm neonate and in the second and third trimester fetus predominantly express a CD45RA^{high}CD45RO^{low} surface phenotype that is characteristic of antigenically naïve T cells found in adults. About 30% of circulating T cells of the full-term neonate are CD45RA^{low}CD45RO^{low}; the cells appear to be immature thymocyte-like cells that are destined to lose expression of the CD45RO isoform and become naïve T cells. Most neonatal CD45RA^{high} T cells express CD31 (PECAM-1), which is involved in cell adhesion, but about 10–20% are CD31⁻. These CD31⁻ CD4 T cells may have undergone homeostatic proliferation, which is triggered in response to unfilled niches in the periphery.¹¹ Cord blood T cells may be more prone than adult naïve T cells to undergo homeostatic proliferation because of a greater sensitivity to the mitogenic effects of IL-7.¹ CD38, an ectoenzyme involved in intracellular calcium mobilization, is expressed on virtually all peripheral fetal and neonatal T cells as well as fetal and postnatal thymocytes. In contrast, CD38 is absent on adult naïve T cells, suggesting that peripheral T cells in the fetus and neonate may represent a thymocyte-like immature transitional population.

CD4 T-CELL RESPONSES

Herpes virus infections

One of the most striking limitations in neonatal T-cell immunity is the reduced and delayed HSV-specific CD4 T-cell proliferation and cytokine (IL-2, IFN- γ , and TNF- α) production in neonates compared to adults after primary HSV infection.^{12,13} Older infants and young children also have reduced CD4 T-cell immunity (IL-2, IFN- γ , and CD40-ligand (CD154) expression) after primary infection with cytomegalovirus (CMV), another herpes virus, compared to adults.¹⁴ This reduced CD4 T-cell response is associated with persistent CMV shedding in the urine and saliva of young children following primary infection. This reduced CMV-specific CD4 T-cell response also likely applies to the neonate and young infant with congenital, perinatal, or postnatally acquired CMV infection, all of whom persistently shed CMV for years following its acquisition.

Vaccines

CD4 T-cell responses to inactivated vaccines may be reduced in young infants and, likely, neonates. Vaccinated infants between 6 and 12 months of age have lower IL-2 production by CD4 T cells in response to tetanus toxoid than older children and adults,¹ suggesting that antigen-specific memory CD4 T-cell generation or function is decreased during infancy.

The robustness of the CD4 T-cell response of the neonate and young infant to live vaccines may vary with the particular agent. Vaccination with bacille Calmette-Guérin (BCG) at birth versus 2 months or 4 months of age is equally effective in inducing CD4 T-cell proliferative and IFN- γ responses to mycobacterial antigens,¹⁵ and does not result in Th2 skewing, i.e., increased production of IL-4, IL-5, and IL-13 and reduced levels of IFN- γ . However, the Th1 responses of infant vaccinees have not been directly compared with those of older children and adult vaccinees. In contrast, the CD4 T-cell response to oral poliovirus vaccine (OPV) may be reduced in the neonate and young infant: Newborns given OPV at birth, 1, 2, and 3 months of age, have lower OPV-specific CD4 T-cell proliferation and IFN- γ production compared to adults immunized in childhood.¹⁶ In contrast, the neonate's and infant's antibody titers are higher than those of adults, suggesting that CD4 T-cell help for B cells is not impaired. It is plausible that OPV may be less effective at inducing a Th1 response than BCG in neonates and young infants because of its limited replication (BCG vaccination results in permanent infection), its site of inoculation, or a more limited ability to stimulate antigen-presenting cells (APCs) in a manner conducive to Th1 immunity.

Mechanisms for reduced immunity

Normal CD4 T-cell activation generates a series of signals following engagement of the $\alpha\beta$ -TCR and CD28 by MHC/peptide and CD80 and CD86 proteins respectively (Fig. 32.1). These include increases in the intracellular level of calcium and others, which activate NFAT-, AP-1-, and NF- κ B-dependent transcription of genes such as IL-2 and CD154. IL-2 promotes CD4 T-cell proliferation in an autocrine and paracrine fashion, and CD154 engages CD40 on the cDC to increase its expression of CD80, CD86, and IL-12p70. In addition to limitations in DC function discussed above, there are multiple potential mechanisms intrinsic to the neonatal CD4 T cell that may limit its ability to expand into memory/

effector Th1 cells that have been revealed by *in vitro* studies using purified naïve CD4 T-cell populations (Fig. 32.1).^{1,17} These impairments include reductions in the neonatal CD4 T cell of fluxes of intracellular calcium,¹⁸ NFAT proteins,¹⁹ IL-2 and CD154 expression, and IL-12-induced STAT4 activation,¹⁷ and decreased Th1 differentiation, as indicated by reduced IFN- γ mRNA and protein expression. The molecular basis for reduced calcium fluxes remains unclear, but a low level of certain NFAT proteins may contribute to reduced IL-2, CD154, and IFN- γ gene transcription. The IFN- γ gene locus may also be more highly methylated in neonatal compared to adult naïve CD4 T cells,²⁰ limiting its accessibility to transcription factors. Reduced CD154 expression may decrease CD40 engagement of cDCs and their production of IL-12p70.¹⁷ Finally, decreased STAT4 signaling, which normally enhances IFN- γ gene transcription, may also impair Th1 differentiation.

CD8 T-CELL RESPONSES

The limited data available suggest that CD8 T-cell responses to herpes viruses, such as CMV, acquired congenitally are similar to those of adults²¹ or the responses to infection acquired in infancy or early childhood.²² Neonates with congenital Chagas disease also have readily detectable CD8 T-cell responses to this pathogen. These apparently robust responses do not rule out a brief, but potentially important, lag in the onset of CD8 T-cell immunity that might compromise the early control of these pathogens.

CD8 T-cell responses to human immunodeficiency virus type 1 (HIV-1) in perinatally infected infants suggest that CD8 T cells capable of mediating cytotoxicity have undergone clonal expansion *in vivo* as early as 4 months of age. However, their cytotoxicity may be reduced and delayed in appearance compared to adults. There is also decreased HIV-1-specific CD8 T-cell production of IFN- γ by young infants after perinatal HIV 1 infection and a limited ability to generate HIV-1 specific cytotoxic T cells following highly active anti-retroviral therapy.²³ The role of HIV-1 itself in impairing these responses is plausible given the multiple mechanisms by which HIV-1 can suppress adaptive immunity. In general, the maintenance of

KEY CONCEPTS

MECHANISMS THAT MAY ACCOUNT FOR DELAYED CD4 T-CELL IMMUNITY TO INFECTION AND VACCINATION IN THE FETUS AND NEONATE

- >> Decreased calcium flux and CD154 (CD40-ligand) expression by naïve CD4 T cells after activation by antigen
- >> Decreased production by conventional dendritic cells of IL-12p70, a key cytokine for Th1 differentiation
- >> Increased methylation of the interferon- γ gene resulting in decreased gene transcription in response to T-cell activation
- >> Decreased expression of STAT4 protein and IL-12-induced STAT4 tyrosine phosphorylation in neonatal CD4 T cells
- >> Reduced expression by neonatal CD4 T cells of NFAT family transcription factors required for CD154 and cytokine gene transcription

HIV-1 specific CD8 T cells with effector function depends on HIV-1 specific CD4 T cells, which tend to be selectively depleted by the virus. Interestingly, the suppressive effects of HIV-1 on CD8 T-cell responses appear to be relatively specific, as HIV-1 infected infants with poor HIV-1 specific CD8 T-cell responses maintain CD8 T cells to herpes viruses.²³

B CELLS

ONTOGENY OF B CELLS

Pre-B cells are first detected in the human fetal liver and omentum by 8 weeks of gestation and in the fetal bone marrow by 13 weeks of gestation. By mid-gestation the bone marrow is the predominant site of pre-B-cell development, and by 30 weeks of gestation it is the sole site. The concentration of B cells in the circulation is higher during the second and third trimesters than at birth and further declines by adulthood. B cells expressing surface immunoglobulin M (IgM) but not IgD are present by 10 weeks of gestation. Such IgM⁺IgD⁻ B cells may be a transitory stage between pre-B cells and mature IgM⁺IgD⁺ B cells. Antigen exposure of IgM⁺IgD⁻ B cells may result in clonal anergy rather than activation, which may be important in maintaining B-cell tolerance to soluble self antigens present at a high concentration. This mechanism may also account for the observation that early-gestation congenital infection sometimes results in pathogen-specific defects in immunoglobulin production.

By 16 weeks of gestation, all heavy-chain isotypes are detectable in fetal bone marrow B cells. The stimulus for this fetal isotype switching remains unclear. The frequency of B cells in tissues rapidly increases so that by 22 weeks' gestation the proportion of B cells in the spleen, blood, and bone marrow is similar to that in the adult. Cord blood B cells expressing surface IgG or IgA are typically very rare (i.e., <1% of circulating B cells). True germinal centers in the spleen and lymph nodes are absent during fetal life, but appear during the first months after postnatal antigenic stimulation.

IMMUNOGLOBULIN REPERTOIRE

The preimmune immunoglobulin repertoire consists of antibodies that can be expressed prior to encounter with antigen and is determined by the number of different B-cell clones with distinct antigen specificity. During early to mid-gestation this repertoire is limited by less diverse usage of V segments, but by the third trimester is as diverse as that of the adult. There may be over- or under-representation of a few V(D)J segments in the neonate, but these are unlikely to limit the quantity or quality of the

neonatal humoral immune response significantly. The length of the CDR3 region of the immunoglobulin heavy chain, which is located at the center of the antigen-combining site, is shorter in the mid-gestation fetus than at birth or in adulthood; this is most likely due to decreased TdT activity. The length of the CDR3 region of the heavy-chain gene gradually increases from the beginning of the third trimester and birth and remains constant thereafter. As the CDR3 region is the most hypervariable portion of immunoglobulins, a short CDR3 region significantly reduces the diversity of the fetal immunoglobulin repertoire and theoretically could compromise the fetal antibody response. However, experiments with mice lacking TdT suggest this would likely be subtle. Instead, a lack of TdT may be important for the fetal development of "natural" immunoglobulin specificities that provide intrinsic protection against pathogens, such as bacteria. Somatic hypermutation appears to occur normally by birth in the B-cell compartment.¹

B1 B CELLS

A distinct feature of fetal and neonatal B cells is their high frequency of CD5 expression, e.g., more than 40% of B cells in the fetal spleen, omentum, and circulation at mid-gestation are CD5^{high}.¹ These CD5^{high} B cells belong to the B-1a subset, which accounts for most production of natural IgM antibodies and also tends to produce antibodies with greater autoreactivity than do conventional B2 cells. These natural IgM antibodies can be considered a part of the innate immune system in providing protection against pathogens, such as certain encapsulated bacteria.

ONTOGENY OF RESPONSIVENESS TO T-DEPENDENT AND T-INDEPENDENT ANTIGENS

The chronology of the antibody response to different antigens differs depending on the need for cognate CD4 T-cell help (Table 32.1). Antigens that depend on cognate help (direct CD4 T-cell–B-cell interactions) include most proteins and polysaccharide–protein conjugates (T-dependent (TD) antigens). The response to TD antigens is characterized by the generation of memory B cells with somatically mutated, high-affinity immunoglobulin and the potential for isotype switching. Antigens that are partially or completely independent of CD4 T-cell help (T-independent antigens) can be divided into T-independent type 1 (TI-1) and type 2 (TI-2) antigens (Chapter 6).

Table 32.1 Postnatal ontogeny of competence for antibody responses to T-cell-dependent (TD) and T-cell independent type 1 (TI-1) and type 2 (TI-2) antigens

Antigen type	Nature of antigen	Age for competent response
TD	Proteins and protein-conjugated polysaccharides	Birth
TI-1	Certain microbial-derived products that directly activate B cells, e.g., <i>Brucella abortus</i>	Birth
TI-2	Unconjugated polysaccharides, such as those from bacterial capsules	Delayed (6–24 months of age)

Table 32.2 Postnatal antibody responses of infants 6 month of age or younger to selected vaccines

Vaccine	Antigen type	Antibody response in neonate and young infant
Diphtheria toxoid	TD	Immunogenic at birth, but response superior when vaccination series delayed until 1 month of age
<i>Haemophilus influenzae</i> type b polysaccharide-conjugate vaccine	TD	Immunogenic at birth, but response superior when vaccination series delayed until 2 months of age
<i>Haemophilus influenzae</i> type b polysaccharide unconjugated vaccine	TI-2	Not reliably immunogenic until 18–24 months of age
Hepatitis B surface antigen	TD	Moderately decreased with vaccination at birth compared to 1 month of age; decreased response in premature compared to term neonate; delay of vaccination series recommended for premature infants of HbsAg- mothers
Meningococcal polysaccharide-conjugated vaccine (types A, C, Y, W-135)	TD	Increased antibody titers in response to vaccination beginning at 2 months of age, with evidence of priming – efficacy?
Meningococcal polysaccharide vaccine – unconjugated (types A, C, Y, W-135)	TI-2	Serotype A immunogenic as early as 3 months of age; other serotypes not reliably immunogenic until 24 months of age; vaccination with type C induces tolerance to subsequent immunization in adults and presumably all age groups
Pertussis vaccine – acellular	TD	Immunogenic when series begun at 2 months of age
Pertussis vaccine – whole cellular	TD	Tolerance to pertussis toxin after vaccination at birth but not at 1 month of age; mechanism?
Pneumococcal polysaccharide-conjugate vaccine – 7 or 11 valent	TD	Protective to majority of serotypes after three doses when series is begun at 2 months of age.
Pneumococcal polysaccharide unconjugated vaccine – 23 valent	TI-2	Not reliably immunogenic until 18–24 months of age for most serotypes
Tetanus toxoid	TD	Protective in vaccinated neonates but relatively delayed response compared to 2-month-old infants

TI-1 antigens directly bind to B cells and fully activate them to produce antibodies, e.g., fixed *Brucella abortus* bacteria. TI-2 antigens include bacterial capsular polysaccharides and require additional signals for optimal antibody production, such as TLR ligands (e.g., unmethylated CpG DNA) that are directly recognized by B cells, or cytokines produced by non-B cells (e.g., NK cells, NK T cells, T cells, or DCs). The response to TI-2 antigens is characterized by a lack of B-cell memory or somatic hypermutation and isotype expression that is largely restricted to IgM and IgG₂.

The capacity of the neonate and young infant to respond to TD antigens is well established at birth, as reflected in the immune response to most protein and polysaccharide conjugate vaccines (Table 32.2). Nevertheless, there are clear differences between neonates and older infants in the magnitude of the antibody response to protein neoantigens. For example, in the case of hepatitis B surface antigen (HBsAg), the initial antibody response in term neonates immunized shortly after birth is substantially lower than if primary immunization is begun at 1 month of age. The neonate's ultimate anti-HBsAg titers achieved after secondary and tertiary immunizations are similar to those of older children, indicating that neonatal immunization does not result in tolerance. Together, these results indicate that the developmental limitations

responsible for reduced antibody responses are transient, although the precise mechanisms remain undefined.

Antibody production by human neonatal B cells to a TI-1 *in vitro* (*Brucella abortus*) is only modestly reduced (Table 32.1) and may reflect a decreased ability of antigen-activated B cells to proliferate rather than a decreased precursor frequency of antigen-specific clones.

The response to TI-2 antigen is the last to appear chronologically, and accounts for the neonate's poor antibody response to infection with encapsulated bacteria, e.g., group B streptococci (GBS) and/or vaccination with unconjugated polysaccharide antigens, such as for *Haemophilus influenzae* and *Streptococcus pneumoniae* (Table 32.2). The response to some unconjugated polysaccharide antigens can be demonstrated by 6 months of age, but the response to vaccination with *H. influenzae* type b capsule, *Neisseriae meningitidis* type C, or to most pneumococcal polysaccharides is poor until approximately 18–24 months. This poor response in children less than 2 years of age is associated with a lack of circulating memory (CD27^{high}) B cells that express IgM and have not undergone isotype switching. These IgM memory B cells are also absent in adults after splenectomy, suggesting they depend on the spleen microenvironment for their generation and/or long-term survival. It is unclear whether decreased TI-2

Fig. 32.2 Immunoglobulin G (IgG), IgM, and IgA levels in the fetus and in the infant in the first year of life. IgG of the fetus and newborn are solely of maternal origin. Maternal IgG disappears by 9 months of age, by which time endogenous synthesis is well established. IgM and IgA of the neonate are due solely to endogenous synthesis because these immunoglobulin isotypes do not cross the placenta. (From Remington JS, Klein JO, Wilson CB, et al. (eds) *Infectious Diseases of the Fetus and Newborn Infant*, 6th edn. Philadelphia: Elsevier; 2006: Fig. 4-10)

antigen responses in early childhood are due to an intrinsic immaturity in B cells or APCs of the spleen or to other limitations in the spleen microenvironment.

■ ANTIBODY RESPONSES OF THE PREMATURE INFANT ■

There is a limited antibody response of premature infants to immunization with protein antigens during the first month of life but not by 2 months of age (Table 32.2). Thus, postnatal age is more of a determinant of antibody responses to TD antigens than is gestational age. This may be of particular clinical relevance for HBsAg vaccine, which in term neonates is effective when given immediately after birth. As in term infants, the antibody responses to TI-2 antigens in premature infants are delayed until 6–24 months of age, depending on the particular antigen.

MATERNAL-FETAL TRANSFER OF IgG

IgG is transported from the mother to the fetus by transcytosis and is detectable in the fetus by 17 weeks of gestation. Circulating concentrations of IgG in the fetus rise steadily and may exceed those of the mother after 34 weeks of gestation, consistent with the transfer being an active transport mechanism. The fetus synthesizes little IgG so that the concentration *in utero* is almost entirely maternally derived (Fig. 32.2). Accordingly, the degree of prematurity is reflected in proportionately lower neonatal IgG concentrations.

FETAL AND POSTNATAL IMMUNOGLOBULIN SYNTHESIS

IgG is the predominant immunoglobulin isotype at all ages (Fig. 32.2). The IgG plasma half-life is about 21 days, and maternally derived IgG levels fall rapidly after birth. IgG synthesized by the neonate and that passively derived from the mother are approximately equal when the neonate reaches 2 months of age; by 10–12 months of age the IgG is nearly all infant-derived. Values reach a nadir of ~400 mg/dl in term infants at 3–4 months of age and rise thereafter (Fig. 32.2). The premature infant has a lower IgG concentration at birth, and reaches a nadir at 3 months of age. The slow onset of IgG synthesis in the neonate is predominantly an intrinsic limitation of the neonate rather than inhibitory effect of maternal antibody, as a similar pattern of IgG development is observed in neonates born to mothers with untreated agammaglobulinemia.

IgM, IgA, and IgE do not cross the placenta. IgM increases from a mean of 6 mg/dl in premature infants less than 28 weeks of gestation to 11 mg/dl at term, which is approximately 8% of the maternal IgM level. This IgM, which is likely to be pre-immune or “natural,” is enriched for polyreactive antibodies produced by B1 cells, and may play a role in the innate defense against infection. Postnatal IgM concentrations rise rapidly in premature and term infants in the first month and then more gradually thereafter, presumably in response to antigenic stimulation (Fig. 32.2). Elevated (> 20 mg/dl) IgM concentrations in cord blood suggest possible intrauterine infections, but this is not a sensitive screen for congenital infections.

IgA has a concentration in cord blood of about 0.1–5.0 mg/dl, approximately 0.5% of the levels in maternal sera. Concentrations are similar in term and premature neonates, and increase to 20% of those in adults by 1 year of age (Fig. 32.2). Increased cord blood IgA concentrations are observed in some infants with congenital infection, and elevated IgA is common in young infants infected by vertical transmission with HIV. IgA has a relatively short half-life in plasma of approximately 5 days. Secretory IgA is present in substantial amounts in the saliva by 10 days after birth.

The concentration of IgE in cord blood is typically only about 0.5% of those of maternal levels. The rate of postnatal increase varies, and is greater in infants predisposed to allergic disease or greater environmental exposure to allergens. The concentration of IgE at birth has limited predictive value for whether an individual will later develop atopic disease.

NK CELLS

The human fetal liver produces NK cells as early as 6 weeks of gestation, but the bone marrow is the major site for NK-cell production from late gestation onward. NK cells are present in greatest numbers in the circulation during the second trimester of fetal development, and comprise ~15% of total lymphocytes in the neonatal circulation, which is typically equal to or greater than in adults. IL-15 appears to play a central role in NK-cell development, suggesting that NK lineage cells in fetus and neonate have normal IL-15 responsiveness. Most surface receptors and markers are expressed at similar levels in neonatal and adult NK cells. An exception is CD56, which is only expressed by about 30–50% of neonatal NK cells compared to >95% of adult NK cells.¹

The cytolytic function of NK cells increases progressively during fetal life to reach values approximately 50% of those in adult cells at term, as determined in assays using tumor cell targets such as the K562 erythroleukemia cells. Full function is not achieved until at least 9–12 months of age. NK cells from the premature infant also have more pronounced reductions in cytotoxic function than those of the term neonate. The reduced cytolytic activity of neonatal NK cells appears to reflect primarily diminished post-binding cytotoxic activity and diminished recycling to kill multiple targets. These functional defects appear to be limited to CD56⁺ neonatal NK cells, and cytolytic activity mediated by neonatal CD56⁺ NK cells is similar to those of adult NK cells. Neonatal NK-cell cytotoxicity can be markedly increased by incubating these cells with a variety of cytokines, e.g., IL-2 or IFN- α , suggesting a potential immunotherapeutic strategy. Limited studies suggest that neonatal NK cells produce IFN- α as effectively as adult NK cells in response to exogenous IL-2 and HSV or to pharmacological stimulation, but the production of other cytokines, such as TNF- α , may be reduced.¹

PHAGOCYTES

NEUTROPHILS

Mature neutrophils are first detected by 14–16 weeks of gestation. At mid-gestation, postmitotic neutrophils constitute only 10% of circulating leukocytes and are also in markedly lower numbers in the bone marrow compared to term newborns and adults. Sepsis and other perinatal

complications can cause neutropenia, and severe or fatal sepsis is often associated with persistent neutropenia, particularly in preterm neonates. Neutropenia may be associated with increased margination of circulating neutrophils, which occurs early in response to infection. Sustained neutropenia often reflects depletion of the neonate's limited postmitotic neutrophil storage pool. Importantly, septic neutropenic neonates in whom the neutrophil storage pool is depleted are more likely to die than are those with normal neutrophil storage pools. Reduced G-CSF production may also be a factor in neutropenia, although this does not appear to be a major mechanism in most cases of neutropenia associated with sepsis.

Neonatal phagocytic function is also limited by reduction or delays in neutrophil migration from the blood to sites of infection and inflammation.²⁴ This may explain why the early inflammatory response in neonatal skin often contains a larger number of eosinophils than in adult skin and why the transition from a neutrophilic to a mononuclear cell-dominated response is delayed in the newborn. The combination of a deficiency in the abundance of L-selectin and ability to shed this protein from the surface of neonatal neutrophils, and decreased binding of these cells to P-selectin may contribute to defective cell adhesion to activated endothelium. Neonatal neutrophil chemotaxis may also be impaired based on *in vitro* studies using leukotrienes, IL-8, and other stimuli. In contrast, phagocytosis and killing by neonatal neutrophils, including by oxidative and nonoxidative mechanisms, are largely intact, but can be compromised when opsonins are limiting or the bacterial density is high. These deficits in uptake and killing are greater in preterm neonates.

MONONUCLEAR PHAGOCYTES

Blood monocytes from neonates are normal in number and similar to adult monocytes in phagocytic and microbicidal activity. By contrast, migration of neonatal monocytes into sites of inflammation, such as delayed-type hypersensitivity reactions, is reduced.¹ Tissue macrophages in neonatal animal models have reduced phagocytic and microbicidal activity and this may also apply to humans. The capacity of mononuclear phagocytes to produce both pro- and anti-inflammatory cytokines may be modestly reduced in term neonates and further reduced in premature neonates. These modest limitations in mononuclear cell function may be compounded by a concomitant deficiency in production of IFN- γ by neonatal T cells and NK cells, and by impaired responsiveness of neonatal mononuclear phagocytes to IFN- γ .¹

HUMORAL MEDIATORS OF INFLAMMATION AND OPSONIZATION

Humoral factors that participate in the response to infection and inflammation include complement components, mannan-binding lectin, fibronectin, and surfactant apoproteins. Compared with adults, neonates have moderately diminished alternative complement pathway activity and slightly diminished classic complement pathway activity. Fibronectin and mannan-binding lectin concentrations are also slightly lower. Consistent with these findings, neonatal sera are less effective than adult sera in opsonization either in the absence of antibody or at low titers of antibody. Generation of complement-derived chemotactic activity is also moderately diminished.

These differences are greater in preterm than in term neonates. Preterm neonates may also have compromised lung defenses as a result of reduced abundance of surfactant apoprotein A. These deficiencies, in concert with phagocyte deficits described above, may contribute to delayed inflammatory responses and impaired bacterial and fungal clearance in neonates.

■ HOST DEFENSE MECHANISMS AGAINST SPECIFIC PATHOGENS ■

HERPES SIMPLEX VIRUS

HSV infection is severe in term infants infected at the time of parturition or postnatally up to 4 weeks of age. Characteristically, neonatal HSV infection spreads rapidly to produce disseminated or central nervous system disease in approximately 60–65% of cases. Deficiencies in the function of neonatal NK cells, cDCs, and pDCs are probably important contributors to the poor early control of infection by the mechanisms of innate immunity. Reduced type I IFN production by neonatal pDCs may be particularly relevant to infection severity, as murine studies suggest that an obligatory interaction between pDCs and cDCs is necessary to generate effective HSV-specific CD8 T-cell responses.³ Fetal and neonatal NK cells have reduced natural and antibody-dependent cytotoxicity against HSV-infected target cells. These decreased NK-cell responses are likely to be relevant, as rare patients with selective NK-cell deficiency are also highly susceptible to severe and early disseminated infection with HSV and other herpes viruses.

As discussed above, HSV-specific CD4 T-cell responses by neonates are diminished and delayed compared to adults following primary HSV infection. Neonates do not achieve adult levels of these responses for 3–6 weeks after clinical presentation, whereas adults develop robust responses within 1 week. Since CD4 T cells provide multiple effector functions that may be critical for the resolution of HSV infection – including direct antiviral cytokine production and help for CD8 T cells and B cells – this marked lag could be an important contributor to the tendency for dissemination and severe organ damage. The basis for the delayed development of HSV antigen-specific CD4 T cells in neonates is not known and could reflect limitations in DC function or intrinsic limitations in the ability of neonatal naïve CD4 T cells to be activated and differentiate into effector cells. The age at which primary infection with HSV in

children results in a similar CD4 T-cell response to that of adults is unknown, but severe or disseminated infection in otherwise healthy infants is extremely rare after 6 weeks of age.

The postinfection kinetics of HSV-specific CD8 T-cell responses in the fetus, neonate, or young infant is unknown, and it is unclear if there is a lag compared to the adult, as has been observed for the CD4 T-cell response. Whether neonates have a reduced HSV-specific antibody response following infection compared to adults with primary infection is also unknown. Passively acquired maternal antibody could play a role in decreasing transmission or ameliorating disease severity in neonatal HSV.

GROUP B STREPTOCOCCI

In the absence of maternally derived type-specific antibodies, the neonate is at risk for GBS infection. There are subtle but cumulative limitations in a number of other host defense mechanisms that account for the marked susceptibility of the neonate to GBS infection.²⁴ For example, neonates lack secretory IgA and have reduced amounts of fibronectin in their secretions compared to older individuals. Reduced amounts of surfactant apoprotein A in the lungs of preterm neonates, a paucity of alveolar macrophages in the lungs, particularly in preterm infants, and diminished phagocytosis and killing of GBS by these cells may facilitate invasion through the respiratory tract. Limitations in the generation of chemotactic factors and/or deficits in the chemotactic responses of neonatal neutrophils may delay recruitment of neutrophils to sites of infection. Neonatal neutrophils that reach sites of infection may kill bacteria less efficiently because of limited amounts of opsonins available for a high local density of GBS, or because the microbicidal activity of neutrophils from certain neonates is decreased. Rapidly progressive infection can deplete the limited marrow neutrophil reserve compounding this problem.

Once GBS infection is established the adequacy of neutrophil production may be critical for preventing morbidity and mortality. Severe or fatal sepsis from GBS is often associated with persistent neutropenia,

KEY CONCEPTS

POTENTIAL MECHANISMS CONTRIBUTING TO THE SEVERITY OF PRIMARY HERPES SIMPLEX VIRUS (HSV) INFECTION OF THE NEONATE

- Reduced type I interferon production by plasmacytoid dendritic cells
- Decreased production of IL-12p70 by conventional dendritic cells
- Decreased natural killer cell-mediated cytotoxicity against HSV-infected target cells
- Diminished and delayed HSV-specific CD4 T-cell responses, including Th1 cells

KEY CONCEPTS

POTENTIAL MECHANISMS THAT MAY CONTRIBUTE TO THE HIGH FREQUENCY AND SEVERITY OF GROUP B STREPTOCOCCAL (GBS) INFECTIONS IN THE NEONATE

- Reduced surfactant apoprotein A in the lungs of preterm neonates
- Decreased numbers of alveolar lung macrophages, particularly in the preterm neonate, that can effectively phagocytose and kill GBS in the lung
- Limitations in the local generation of chemotactic factors and/or deficits in the chemotactic responses of neonatal neutrophils
- Decreased neutrophil killing at sites of infection because of limited amounts of opsonins and, in some individuals, neutrophil microbicidal activity
- Limited neutrophil storage pool in bone marrow compartment – important cause of neutropenia in overwhelming infection

particularly in preterm neonates, and most likely reflects the depletion of the postmitotic neutrophil storage pool in the bone marrow.

The use of intravenous immunoglobulin or subcutaneously administered colony-stimulating factors in the prevention or treatment of neonatal GBS and other pyogenic infections is theoretically attractive. However, an analysis of the outcome of multiple clinical trials suggests that this approach or the use of white blood cell transfusions in cases of established sepsis do not consistently reduce mortality.^{1, 25}

SUMMARY

Careful evaluation of components of the innate and acquired immune systems of the human fetus and neonate reveals both quantitative and qualitative deficiencies. Increased bacterial infections of the neonate, as seen in neonatal nurseries and intensive care units in major medical centers, result from impaired production or function of soluble factors such as secretory IgA, opsonins, pulmonary surfactant, and defective mobility and chemotaxis. Increased viral infections in neonates obtains from functional deficiencies of NK cells, cDCs, and pDCs as well as diminished and delayed CD4 T-cell responses that stimulate cytolytic CD8 T cells. Thus, the very beginning of life is marked by a period of high risk for infection. Better countermeasures are needed for the protection of infants during this time.

Aging and the immune system

Rania D. Kovaïou, Birgit Weinberger,
Beatrix Grubeck-Loebenstien

33

Worldwide, the segment of the population aged 60 or over is increasing rapidly. This demographic change represents one of the most challenging problems in many countries, as it puts pressure not only on individuals and their families but also on the social security system, which has to deal with the tremendous costs of medical care for the elderly. It is therefore of great interest to society that measures are taken which contribute to healthy aging and prolong the period of life that is not compromised by age-associated deficits.

The immune system undergoes profound age-related changes, collectively termed immunosenescence. Aging affects a wide range of cell types, including hematopoietic stem cells (HSCs), lymphoid progenitors in the bone marrow and thymus, thymic stroma, mature lymphocytes in secondary lymphoid organs, and elements of the innate immune response. At the functional level, these changes are translated into an increased susceptibility to infections and suboptimal vaccine-induced protection. Furthermore, infections in the elderly are characterized by more severe symptoms, prolonged duration, and poorer prognosis. Well-known examples of infections that specifically affect the elderly are the reactivation of the varicella-zoster virus leading to herpes zoster in individuals over 50 years of age, and infection with influenza virus associated with an increased risk of severe complications. Additionally, risks for

bacterial pneumonia, urinary tract infection, pneumococcal and *Listeria* meningitis, infection with *Mycobacterium tuberculosis* and viral gastroenteritis are increased in the elderly.¹

Although intensive research over past decades has attempted to clarify the basic mechanisms of age-related immune dysfunction, the exact nature of the underlying defects is not yet fully understood, but owing to coordinated efforts by laboratories worldwide focusing on immunosenescence and our increasing knowledge of the biology of the immune system, a convincing and clear-cut picture has started to emerge. It is the goal of this chapter to summarize recent reliable data on the cellular and molecular mechanisms of immunosenescence, and to try to interpret how basic dysfunctions may eventually lead to disability and disease in the elderly.

■ THE EFFECT OF AGING ON HEMATOPOIETIC STEM CELLS AND LYMPHOID PROGENITOR CELLS ■

It is well understood that the amount of hematopoietic tissue in the human bone marrow decreases with age.² Studies on humans and various animal models have indicated that HSCs are severely affected: the ability of human HSCs to proliferate correlates inversely with age, and HSCs have shortened telomeres, which may affect their proliferative and developmental potential. Age-related perturbations in the hematopoietic microenvironment combined with changes in hormones, such as the anterior pituitary-derived growth hormone, also disturb HSC self-renewal and lineage commitment.

Age-related changes to HSCs seem to affect lymphoid, but not erythroid and myeloid, progeny cells. Fewer pro-B cells are generated and fewer of these cells transit into the pre-B and B-cell pools. As a result, the total number of pre-B cells is reduced and fewer new mature B cells leave the bone marrow.³ Bone marrow-derived T-lymphocyte precursors continuously migrate into the thymus, where they mature. The frequency and absolute numbers of intrathymic T-cell progenitors decrease with age.⁴ This is partly due to age-related changes in the bone

KEY CONCEPTS

GENERAL INFORMATION ON AGING

- >> Aging is usually defined as the progressive loss of function accompanied by decreasing fertility and increasing mortality with advancing age.
- >> Aging begins at the moment an organism is born and is inevitable throughout life.
- >> Aging influences various systems of the organism (nervous system, endocrine system, immune system).
- >> Aging represents one of the most challenging problems of the developed countries owing to prolongation of lifespan.

Fig. 33.1 (A) Pediatric thymus showing division into cortical (outer darker staining) and medullary (inner lighter-staining) areas, with lobules separated by thin septa. (B) Chronic involution with aging. Thymus from an 82-year-old individual showing dramatic reduction of lymphoepithelial elements (true thymus), and invasion of adipose tissue into the septa and intrathymic region immediately under the capsule. (Hematoxylin staining. Magnification $\times 250$.) (From George AJ, Ritter MA. Thymic involution with ageing: obsolescence or good housekeeping? *Immunol Today* 1996; 17: 267, with permission from Elsevier.)

marrow, but is predominantly the result of thymic involution. Thymic function is at its most active during the fetal and perinatal periods, but output declines with age, resulting in a dramatic loss in the number of naïve T cells being produced. This decline in *de novo* T-cell production correlates with the atrophy of the thymic stroma. After puberty there is a gradual loss of thymic tissue, but the thymus can respond to T-cell lymphopenia in adulthood with renewed output of antigenically naïve T cells, such as happens with HIV infection, most likely due to the increased production of interleukin (IL)-7.⁵ Elderly persons retain a very limited thymic function, with thymocytes being produced by a small thymic rudiment composed of epithelium (Fig. 33.1). TCR excision circle (TREC) analysis has been successfully used to study the age-related decline of thymic T-cell output by quantifying the amount of episomal DNA circles that are produced during the rearrangement of $\alpha\beta$ TCR genes.^{5,6}

ADAPTIVE IMMUNITY AND AGING

T LYMPHOCYTES

Although the size of the mature T cell pool remains stable over the lifetime of an individual, the proportionate representation of different subsets and T cell function is greatly affected by aging.

One of the most profound age-related changes in the T-cell population is a decrease in the number of antigen-inexperienced naïve T lymphocytes combined with an increase in antigen-experienced memory and effector cells (Fig. 33.2). Although a diverse naïve CD4 T-cell compartment is maintained for decades in spite of minimal thymic function, a dramatic and sudden collapse of diversity occurs after the age of 70, which results in a severely contracted repertoire.⁷ Similar changes in the CD8 T-cell pool occur even earlier in life.⁸ As a result, the host's ability to respond to new antigens decreases. At the same time a progressive increase in antigen-experienced T cells occurs. Many of these cells do not express the co-stimulatory molecule CD28. Loss of CD28 expression in T cells is one of the most consistent biological indicators of aging in the human immune system.⁹ CD28⁺ T cells are long-lived lymphocytes with a

Fig. 33.2 T-cell subpopulations in youth and old age. Naïve, memory and effector T cells of different specificities are represented by different colors. All three populations are found in young and elderly persons, but their relative proportions change. With age the number and diversity of naïve cells decline as thymic output decreases. Repeated antigenic stimulation eventually leads to an increase in memory T cells and gives rise to highly differentiated, expanded effector clones, resulting in an increase in the size of the effector population that has, however, a very restricted repertoire.

limited proliferative capacity. CD28⁺CD8⁺ T cells may be CD27⁺ (another co-stimulatory molecule) or CD27⁻. In contrast, CD28⁺CD4⁺ T cells are strictly CD27⁻. The loss of CD28 in CD4 T cells is accompanied by a concomitant defect in CD154 (CD40L) expression, hence the capacity of CD4 T cells to provide help for B-cell proliferation and antibody

production is reduced. CD28⁺CD8⁺ as well as CD28⁺CD4⁺ T cells produce large amounts of interferon (IFN)- γ and perforin, and express a variety of killer cell immunoglobulin-like receptors (KIRs). CD28⁺ T cells frequently exhibit specificity for persistent viruses, mainly for cytomegalovirus (CMV), but also for Epstein-Barr virus (EBV) and hepatitis C virus (HCV). A high frequency of these cells has been correlated with a low humoral immune response to influenza vaccination in elderly persons.¹⁰ CD28⁺ T cells characteristically occur as large expanded clones. Expanded clones of CD8 T cells are common in old age and mostly large enough to distort the $\alpha\beta$ T-cell repertoire. The outgrowth of CD4 T cell clonotypes is much less common and occurs mainly in diseases such as rheumatoid arthritis.⁷

At the cellular level, the activation potential of T cells is altered in old age, leading to hyporesponsiveness. This has been well documented in CD4 T cells from mice and humans, and has been attributed to alterations in the formation of the immunological synapses between T cells and antigen-presenting cells, as well as to signaling defects.¹¹ Age-related changes in lipid raft polarization have recently been suggested to represent an important cause of age-related changes in CD4 T-cell signaling.¹² Lipid rafts are dynamic structures, and the time-dependent recruitment or exclusion of signaling proteins in lipid rafts controls T-cell activation and immune responses. Changes in lipid raft properties in the elderly are due to an age-related increase in the cholesterol content of the CD4 T-cell plasma membrane. Corresponding changes in the composition of the CD8 T-cell membrane have less effect on T-cell activation.

Cytokines are a key component in the regulatory communication process among immune cells in general, and T cells in particular. Age-related changes in cytokine production have been studied for over 20 years.¹³ The long-standing notion that IL-2 production decreases while IL-4 production increases with advancing age, has recently been challenged by reports indicating an increase in proinflammatory activity in all organs, which seems at least partly due to an increase in the whole-body load of IFN- γ . The increase in the production of IFN- γ is presumably the result of the pronounced accumulation of terminally differentiated CD28⁺ T cells with a high proinflammatory activity, which is found in large subgroups of elderly persons. In contrast, high IL-4 production, which is observed in other elderly cohorts, correlates with a high number of central memory but a low number of effector T cells.¹⁴

Thymic involution can also lead to a decreased output of regulatory T cells (Tregs). Tregs mostly express high levels of the IL-2 receptor α chain (CD25) and the forkhead and winged-helix family transcription factor forkhead box P3 (FOXP3). Treg homeostasis may still be sustained by alternative pathways such as peripheral generation. Treg-mediated suppression has been reported to decline after the age of 50, and may contribute to age-related phenomena such as increased inflammation and autoimmunity.¹⁵

B LYMPHOCYTES

Like the T-cell pool, the peripheral blood B-cell pool fills up with memory cells owing to a concurrent displacement of naïve cells. The percentage of naïve B cells, which are defined by the absence of CD27, is significantly lower in the elderly than in the young, whereas the opposite is true for memory cells.¹⁶ The production of peripheral blood B cells is similar in elderly and young persons, although there is a trend towards a

slower rate of proliferation in the elderly. Similar to the T-cell pool, aging is associated with the appearance of B-cell clonal expansions. This limits the diversity of the B-cell repertoire and may induce monoclonal serum immunoglobulins and B-cell neoplasms.¹⁷ Additionally, there is a shift from B2 to B1 lymphocytes. Most foreign protein antigens stimulate B2 cells in the presence of T-cell help, whereas carbohydrate and autoantigens do not depend on T-cell help and stimulate B1 cells.

Age-related changes in the B-cell pool result in impaired humoral immunity in the elderly. Primary antibody responses in aged humans are often weak and short-lived, and the antibodies produced bind with lower affinity. Antibody production by elderly persons in response to vaccination has been extensively studied, and it has been suggested that the protective effect of vaccinations against *Streptococcus pneumoniae*, influenza, hepatitis B and tetanus is reduced with age. Old age is also associated with an increased occurrence of autoantibodies. However, these autoantibodies lack specificity for organs and rarely contribute to autoimmune disease.¹⁸

Although age-related changes in humoral immunity may be the result of intrinsic defects in B cells and change in the B-cell repertoire, the lack of the regulatory control of T cells on B cells also contributes to the low-level and brief production period of specific antibodies to foreign antigens in the elderly. CD4 T-cell help is crucial for germinal center (GC) formation. Cognate help from CD4 T cells drives the formation of GCs and enables isotype switching and affinity maturation of antibodies. A defective T-helper function at a higher age thus leads to diminished high-affinity responses in germinal centers.¹⁹ A severe reduction in germinal center reactions has been reported in mice >22 months of age.²⁰ This reduction occurs gradually, and both the number and the volume of germinal centers diminish progressively (Fig. 33.3). The most important age-related changes in the adaptive immune system are summarized in Table 33.1.

INNATE IMMUNITY AND AGING

Innate immunity provides the basis for an adequate response to pathogens. It has to be tightly controlled, as excessive responses can be detrimental. However, with increasing age inflammatory processes occur ubiquitously in a variety of species and characteristically lead to a progressive proinflammatory status referred to as 'inflamm-aging'.²¹ It is by now well understood that chronic inflammation supports the development and progression of age-related diseases, such as osteoporosis, atherosclerosis and neurodegeneration.²²

At first sight, reports on enhanced inflammatory activity in old age seem to be contradicting studies demonstrating functional defects within cells of the innate immune system (Table 33.2). The accumulation of functional defects at the cellular level can, however, lead to an inability to eliminate pathogens and to a chronic ineffective activation of nonspecific responses as a consequence. The severity of inflammatory processes in old age may also depend on genetic factors, for example polymorphisms within the genes encoding for cytokines such as IL-6, IL-10 and IFN- γ , which have also been shown to be associated with changes in lifespan.²³

Age-related changes in the function of neutrophilic granulocytes are well documented. Although their number remains constant, the production of superoxide anion in response to GM-CSF and Gram-positive bacteria is reduced in old age. Additionally, changes in membrane fluidity, chemotaxis to selected chemoattractants and various signal transduction

Fig. 33.3 Progressive decline in germinal center formation during aging. Spleens of C57BL/6 mice immunized 14 days earlier with NP-CGG precipitated in alum were prepared for immunohistologic or flow-cytometric analysis. For enumeration of GC (purple bars), splenic sections were stained with PNA-HRP and GCs were counted under a light microscope. For enumeration of GC cells (green bars), a single-cell suspension of splenocytes was stained with anti-B220 and GL-17 antibodies and analyzed by flow cytometry. (From Zheng B, Han S, Takahashi Y, et al. Immunosenescence and germinal center reaction. *Immunol Rev* 1997; 160: 63, with permission from Blackwell Publishing Ltd.)

pathways have been observed.²⁴ These defects lead to a reduced bactericidal activity of neutrophilic granulocytes in old age.

Monocytes and macrophages are also affected by the aging process. An increasing number of studies shows that, similar to granulocytes, aging macrophages have an impaired respiratory burst and a reduced capacity to produce superoxide anion and nitric oxide. They have defective Toll-like receptor (TLR) expression and are unable to upregulate the expression of MHC class II genes, thus impairing their capacity to present antigen and to trigger CD4 T-cell responses. Owing to functional defects, macrophages from elderly persons may fail to eliminate pathogens. This dysfunction results in chronic activation and the prolonged production of TNF- α and IL-6, but may at the same time

KEY CONCEPTS

AGE-RELATED CHANGES OF THE IMMUNE SYSTEM

- >> Decreased output of lymphoid precursor cells from the bone marrow.
- >> Involution of the thymus.
- >> Decrease of naïve T cells and accumulation of highly differentiated effector T cells.
- >> Impaired humoral immunity.
- >> Impaired function of NK cells, granulocytes and macrophages.
- >> Proinflammatory status.

increase the susceptibility to and severity of bacterial, mycotic and viral infections.²⁵

The number of natural killer (NK) cells increases with age. However, NK-cell cytotoxicity and the production of cytokines and chemokines in response to activation are impaired on a per-cell basis. Probably owing to a partial loss of the high-affinity IL-2 α -chain receptor, proliferation of NK cells from healthy elderly donors in response to IL-2 is reduced.²⁶

Whether dendritic cells (DC) are affected by aging is still unclear. Experiments in mice suggest that the density of DC in the skin, the expression of MHC class II and other cell surface molecules, and the capacity of DC to present antigen can all be altered with increasing age. However, only a few studies have been carried out to analyze these effects in humans.

THE ROLE OF CYTOMEGALOVIRUS (CMV) IN IMMUNOSENESCENCE

Aging is not only a major risk factor for infection, but infection itself may also contribute to the aging of the immune system, as repeated exposure to antigens directly influences immunological aging. Cytomegalovirus (CMV), a herpes virus that establishes lifelong persistence after primary infection, leads to characteristic changes in the CD4 and CD8 T-cell compartments. Comparative studies of CMV-seropositive and -seronegative aged individuals show that the age-related decrease of naïve T cells and the accumulation of CD28⁻ effector cells is strongly increased in CMV-seropositive persons (Fig. 33.4A).

The potential role of CMV and immunosenescence in healthy aging is emphasized by longitudinal studies. These studies, which enrolled individuals over the age of 86 years with a follow-up of up to 8 years, showed that a 2-year mortality can be predicted using immunological parameters summarized as 'immune risk phenotype' (IRP). The IRP is characterized by high numbers of CD8 and low numbers of CD4 T cells, leading to a CD4:CD8 ratio of <1 and a poor response of T cells after stimulation with mitogens. IRP is also associated with CMV seropositivity.²⁷

In addition to the changes in the total T-cell pool, the phenotype and functional properties of CMV-specific T cells have been of particular interest. Most studies focus on CD8 T cells that are specific for the

Table 33.1 Age-related changes within the adaptive immune system

Cell type	Age-related changes
T cells	<ul style="list-style-type: none"> ↓ Naïve T-cell counts due to involution of the thymus ↑ Memory and effector T-cell counts ↓ Diversity of the T-cell repertoire due to the accumulation of expanded clones of effector cells ↓ Expression of co-stimulatory molecules (CD28, CD27, CD40L) ↑ Expression of senescence-associated molecules (CD57, KLRG-1) ↓ Proliferative capacity ↓ T-cell signaling ↓ Activation of naïve T cells
B cells	<ul style="list-style-type: none"> ↓ Generation of B-cell precursors ↑ Number of B1 cells ↓ Diversity of the B-cell repertoire ↓ Size and number of germinal centers ↓ Expression of co-stimulatory molecules (CD27, CD40L) ↓ Antibody affinity ↓ Isotype switch ↓ Serum antibodies specific for foreign antigens ↑ Serum antibodies specific for self-antigens ↓ Stimulation of B cells by follicular dendritic cells

Table 33.2 Age-related changes within the innate immune system

Cell type	Age-related changes
Neutrophils	<ul style="list-style-type: none"> ↓ Oxidative burst ↓ Bactericidal activity ↓ Chemotaxis
Macrophages	<ul style="list-style-type: none"> ↓ Phagocytic capacity ↓ Oxidative burst ↓ MHC class II expression
NK cells	<ul style="list-style-type: none"> ↑ Number of cells ↓ Cytotoxicity ↓ Production of proinflammatory cytokines and chemokines ↓ Proliferative response to IL-2

immunodominant HLA-A2 restricted epitope NLVPMVATV, derived from the viral surface protein pp65 (aa 495-503). CMV-specific CD8 T cells of elderly donors derive from only a few clones after extensive expansion *in vivo*: representing up to several percent of the total CD8 population, they frequently dominate the repertoire (Fig. 33.4B). These cells are characterized by an effector CD28-CCR7-CD57⁺ phenotype. In contrast, a significant proportion of CMV-specific T cells from young donors exhibit a naïve (CCR7⁺CD45RA⁺) phenotype. These findings indicate that CMV infection drives CD8 T-cell differentiation and induces premature immunosenescence, with a loss of functional

CMV-specific naïve and, in the case of CD8 cells, also of memory T cells in the elderly.

It has been reasoned that the immune system is chronically fighting CMV at the expense of the capacity to respond to other pathogens. Responsiveness to new as well as to recall antigens can be impaired because the expanded CMV-specific clones fill up the immunological space, and this leads to a shrunken repertoire of other specificities. In accordance with this hypothesis, an age-related increase in Epstein-Barr virus (EBV)-specific T cells has been observed in CMV-negative donors but not in CMV-seropositive individuals.²⁸ Additionally, lower success rates for influenza vaccination²⁹ and a faster progression of AIDS³⁰ are associated with CMV seropositivity.

The fact that persistent infection with CMV substantially influences immunological aging raises questions about the role of other persistent pathogens, especially other herpes viruses, in immunosenescence. It has been shown that in contrast to CMV-specific T cells, EBV-specific CD8 T cells are mainly CD28⁺, indicating a lesser degree of differentiation. However, the influence of EBV on the aging immune system is not well studied, as nearly 100% of the elderly population are infected with EBV, making comparative studies of EBV-positive and -negative individuals virtually impossible. It should be taken into consideration that other persistent or recurrent pathogens might also play a role in the complex process of immunological aging.

VACCINATION IN THE ELDERLY

Vaccination is highly effective for preventing morbidity and mortality and is therefore especially required in old age. However, the protective effect of vaccination is partially lost in the elderly.³¹ This holds true for

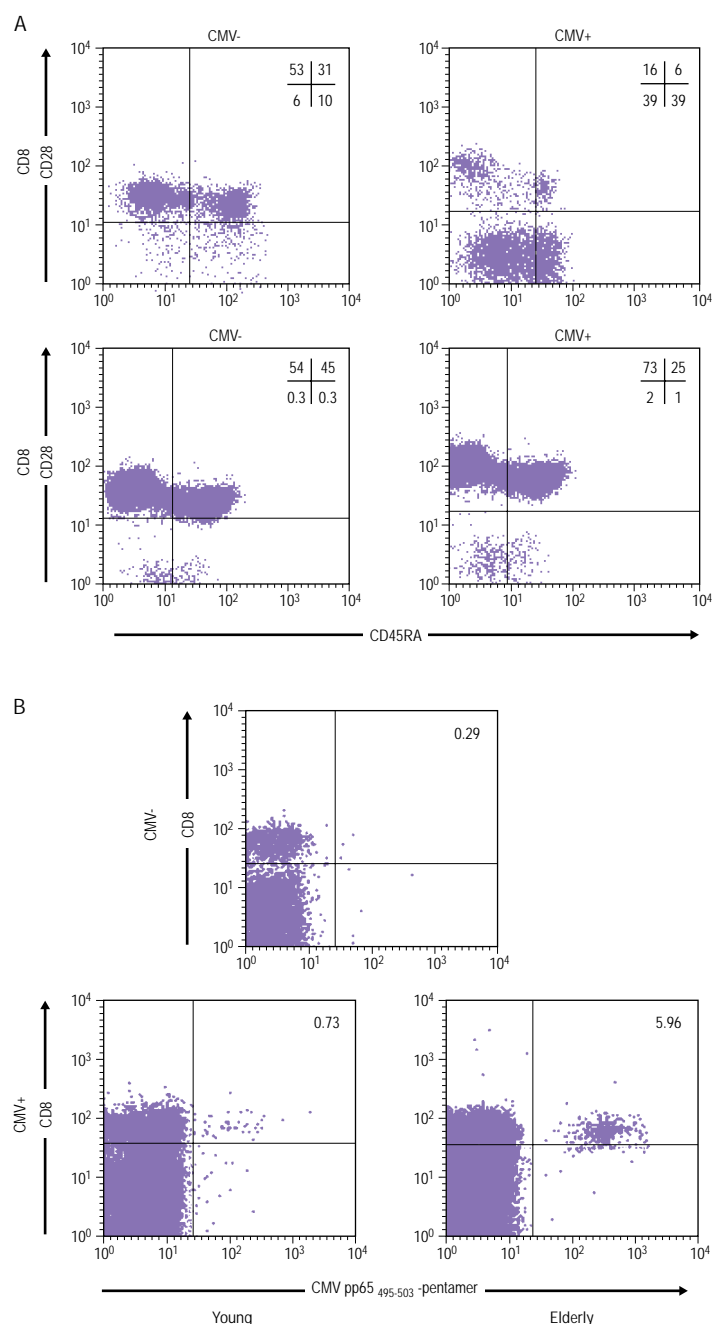

Fig. 33.4 (A) T-cell subpopulations from a CMV-seronegative and a CMV-seropositive elderly person. FACS analysis after staining with CD45RA-FITC and CD28-PE antibodies. The percentages of the respective CD8 (top panel) and CD4⁺ cell subsets (bottom panel) are shown in the quadrants. CD8/CD4 T cells respectively are considered as 100%. For the CD8⁺ population the size of the CD28⁺CD45RA⁺ (naïve) and the CD28⁺CD45RA⁻ (memory) T-cell populations is characteristically decreased, whereas the percentage of CD28⁻ (effector) T cells is increased during latent CMV infection. Within the CD4⁺ population the percentage of naïve T cells also decreases, whereas that of memory cells increases. The percentage of CD28⁻ effector cells is low, but still higher than in persons with a negative CMV serology. **(B)** Age-related changes in the frequency of CMV-specific CD8 T cells. FACS analysis of unstimulated CMVpp65₄₉₅₋₅₀₃ pentamer binding T cells in a CMV antibody-negative elderly donor and in one young and one elderly person with a positive CMV serology. In the upper right corner percentages of CMV-specific cells are shown. CD8 T cells are considered as 100%.

CLINICAL RELEVANCE

CLINICAL CONSEQUENCES OF IMMUNOSENESCENCE

- >> Increased susceptibility to infectious diseases.
- >> Enhanced severity of infections leading to increased morbidity and mortality.
- >> Partial loss of vaccination efficacy.
- >> Increase of autoreactivity.

THERAPEUTIC PRINCIPLES

POTENTIAL STRATEGIES TO OVERCOME IMMUNOSENESCENCE

- >> Reconstitution of the thymus.
- >> Reduction of antigenic stimulation.
- >> Eradication of CMV infection.
- >> Depletion of dysfunctional senescent T cells.
- >> Optimization of vaccines and vaccination strategies.

vaccinations against new antigens (e.g., yellow fever, rabies, new influenza strains) as well as for regularly administered vaccines (e.g., recurrent influenza strains, *Streptococcus pneumoniae*, tetanus, diphtheria, tick-borne encephalitis or hepatitis A). For instance, a meta-analysis of influenza vaccinations revealed a protection rate of only 56% in elderly persons after vaccination,³² despite the fact that influenza is ranked among the 10 major causes of deaths in people over 65. Similarly, polysaccharide vaccines offer protection against invasive pneumococcal disease in only 65% of the elderly population.

There is thus a tremendous need to develop more immunogenic vaccines that specifically address the requirements of the aged immune system. Antigen delivery systems that convert soluble protein antigens into particulate material, which is more readily ingested by antigen-presenting cells, and immunomodulatory adjuvants can be used to overcome the age-related functional impairment of the innate immune response and to enhance the immunogenicity of subunit vaccines. In general, live-attenuated vaccines (e.g., against varicella, measles or yellow fever) are highly immunogenic by inducing long-lasting antibody production and high numbers of memory T and B cells. However, because immune function is impaired in the elderly there is an increased risk of systemic side effects when such viruses are used. For vaccination against polio it has been shown that a primary dose of live-attenuated vaccine early in life enables efficient booster with subunit vaccines in the elderly. Thus, immunization with live-attenuated virus in earlier life followed by inactivated booster vaccination in old age may be a reasonable strategy for efficient protection without the risk of complications. Shortened intervals between booster vaccinations may also be recommended for the elderly in order to sustain protective antibody titers.³³ Vaccination with peptide-loaded dendritic cells, which accelerates the generation of memory T cells, may be another possible approach for inducing a better immune response in the elderly.

STRATEGIES TO REVERSE OR DELAY IMMUNOSENESCENCE

THYMUS RECONSTITUTION

Thymic involution is a key event for the age-associated deterioration of immune function. For this reason, interventionist therapies aiming to rejuvenate the thymus and restore thymic output are a major challenge. Current attempts are based on the administration of IL-7³⁴ or growth

hormone (GH) and IGF-1.³⁵ Administration into aged animals has shown that each of these mediators promotes thymopoiesis and stimulates thymic regrowth, but none of them alone managed to fully restore the thymic mass. Combinations of hormones (e.g. GH and IGF-1) and cytokines (e.g. IL-7) may yield greater effects on cellularity and thymic output.³⁶

REDUCTION OF ANTIGENIC STIMULATION

The prevention of lifelong stimulation of the immune system with certain immunodominant antigens could reduce the accumulation of highly differentiated proinflammatory T cells that occupy immunological space and represent a basis of ubiquitous subclinical inflammatory processes. This could be achieved by eradicating chronic bacterial (e.g., in the oral cavity, the gastrointestinal tract and the urogenital tract) or viral (e.g., herpes viruses) infections. CMV is a driving force of immunosenescence, and early childhood vaccination against CMV might be one option to prevent CMV infection and CMV-associated accelerated immunosenescence. Treatment of CMV with antiviral therapies (e.g. valaciclovir) has also been discussed, but as it is unclear whether this medication leads to full eradication of the virus, long-term treatment would be needed to keep the viral load low; side-effects must also be taken into consideration.

DEPLETION OF SENESCENT T CELLS

Clonally expanded senescent T cells with specificity for antigens such as CMV compete for immunological space with T cells having specificity for other pathogens. Thus, the idea of depleting those T cells in the elderly in order to improve immune function and rejuvenate the immune system seems intriguing. However, it must be emphasized that for this approach it would be necessary to target only senescent T cells, not functionally intact T cells in earlier differentiation stages. KLRG-1 and CD57 have been suggested as surface markers for senescent T cells and could be used for sorting procedures.

CALORIC RESTRICTION

Experiments over the last few decades have shown that a 30% reduction of caloric intake supplemented with vitamins and essential elements to avoid malnutrition leads to longer life in invertebrates (*Caenorhabditis elegans*, *Drosophila melanogaster*), rodents (mice, rats, hamsters) and other vertebrates (zebra fish, birds). Caloric restriction appears to slow down

many aspects of the aging process via various postulated mechanisms, including the delay of immunosenescence. In order to elucidate the possible effects of long-term caloric restriction on the human immune system, studies using rhesus macaques as a nonhuman primate model are now being conducted. Although it is still too early to determine whether caloric restriction also leads to longevity in primates, prevention of typical age-related immunological changes has been shown. Thus, dietary restriction prevents the age-related loss of naïve cells, the accumulation of memory and effector T cells, and the decrease in the proliferative capacity after antigenic stimulation.³⁷

Primary antibody deficiencies

Harry W. Schroeder Jr.

34

Primary antibody deficiency diseases are characterized by an impairment in the ability of the host to produce protective antibodies in response to hazardous antigens.¹ The impairment can be present from birth or it may be acquired at a later age. In some cases, the deficiency may either resolve or worsen with time.² Many of these diseases are caused by loss-of-function or altered-function mutations in genes involved in the regulation of B-cell differentiation. Others reflect mutations in the immunoglobulin genes themselves. In some of the most common conditions, a genetic predisposition has been well documented, but the underlying defect remains unclear. The typical patient presents with a history of recurrent upper respiratory or pulmonary infections and exhibits reduced serum concentrations of one or more classes of immunoglobulin (IgM, IgG, or IgA). However, patients with normal serum immunoglobulin levels may exhibit specific deficits in their ability to mount a protective response against certain antigens, and some virtually agammaglobulinemic patients can be remarkably asymptomatic. The classification of primary antibody deficiency diseases is listed in Table 34.1.

These disorders of humoral immunity can best be understood as the products of specific defects in B-cell differentiation (Chapter 8). Differentiation begins in the fetal liver, and shifts to the bone marrow in the latter stages of fetal life (Fig. 34.1). Maturing B cells are released from these primary lymphoid organs and migrate via the blood into the secondary lymphoid organs, primarily the spleen but also the lymph nodes. Contact with a polymeric cognate antigen, such as a polysaccharide, activates the B cell and allows it to differentiate into an antibody-producing plasma cell. The response to protein antigens, including toxins and viral proteins, requires T-cell help. In the germinal centers, B cells can replace the heavy (H)-chain constant domain with a downstream one, e.g., IgM to IgG₁, and they can induce a high level of mutations in the variable domains, which helps form-fit the antibody to the antigen, a process termed affinity maturation.

CLINICAL MANIFESTATIONS

Patients with antibody deficiencies most commonly present with a history of recurrent sinusitis, otitis media, bronchitis, and pneumonia. These infections typically involve encapsulated bacterial pathogens such as

CLINICAL PEARLS

CLINICAL MANIFESTATIONS OF ANTIBODY DEFICIENCY

>> Recurrent bacterial infections

- >> Early in untreated disease, infections are primarily due to encapsulated pyogenic bacteria (e.g., *Streptococcus pneumoniae* and *Haemophilus influenzae* type b)
- >> Later in untreated disease, damage to mucosal surfaces engenders susceptibility to staphylococci, nontypable *H. influenzae*, and Gram-negative rods, as well

>> Recurrent viral infections

- >> In most cases, viral infections are cleared normally, but protective immunity does not develop. For example, recurrent shingles can be a common symptom in untreated patients
- >> In some cases, patients may continue to excrete virus after resolution of their clinical symptoms

>> Increased prevalence of other immunologic disorders

- >> Paradoxical increased risk of antibody-mediated autoimmune disorders, such as idiopathic thrombocytopenia, autoimmune thyroiditis, systemic lupus erythematosus, and celiac disease

>> Lymphoid hypertrophy

>> Increased risk of allergic disorders

- >> Especially among patients with immunoglobulin A deficiency

Streptococcus pneumoniae and *Haemophilus influenzae*. Protection against these bacteria requires production of anti-polysaccharide antibodies, which does not require T-cell help. A similar susceptibility for infection is seen among patients who are deficient in neutrophil function or in the pivotal third component of complement (C3). Thus, all three of these

Table 34.1 Primary antibody deficiencies

Disorder	Gene or locus	Chromosome
IgA deficiency (IgAD)/common variable immunodeficiency (CVID)		
IgAD/CVID (cause unknown)	MHC	6p21.3
TACI deficiency	TNFRSF 13B	17p11.2
ICOS deficiency	ICOS	2q33
BAFF-R	TNFRSF13C	22q13.1-q13.31
CD19 deficiency	CD19	16p11.2
Transient hypogammaglobulinemia of infancy (THI)		
X-linked agammaglobulinemia	BTK	Xq21.3-q22
X-linked agammaglobulinemia with growth hormone deficiency	BTK	Xq21.3-q22
Hyper-IgM syndrome		
X-linked hyper-IgM syndrome (XHIGM)	HIGM1	Xq26
Activation-induced cytidine deaminase (AID) deficiency	HIGM2	12p13
CD40 deficiency	HIGM3	20q12-q13.2
Uracil-DNA glycosylase (UNG) deficiency	HIGM5	12q23-q24.1
XHM with ectodermal dysplasia (XHM-ED)	IKBKG, NEMO	Xq28
Autosomal agammaglobulinemia		
Immunoglobulin-associated beta (Igβ) deficiency	CD79B	17q23
Immunoglobulin μ H-chain deficiencies	IGHG1	14q32.33
BLNK deficiency	BLNK	10q23.2
Surrogate light-chain deficiency	IGLL1	22q11.21
LRRC8 truncation	LRRC8	9q34.13
Selective immunoglobulin G subclass deficiencies		
Immunoglobulin γ H-chain deficiencies	IGHG1	14q32.33
Selective κ light-chain deficiency	IGKC	2p11.2
Selective λ light-chain deficiency		
Antibody deficiency with normal serum immunoglobulin levels		
Vκ A2 deficiency	IGKV2D-29	2p11.2

arms of the host defense system should be evaluated in patients who suffer with recurrent bacterial infections.

The clinical course of uncomplicated primary infections with viruses such as varicella-zoster or mumps does not differ significantly from that of the normal host. However, antibody-deficient patients have difficulty generating long-lasting immunity, thus chickenpox may repeatedly recur as shingles. This suggests that, while T

cells are sufficient to control established viral infections, antibodies function best to limit the initial dissemination of virus and prevent re-infection. There are exceptions to this general rule. Hypogammaglobulinemic patients can have difficulty clearing hepatitis B virus from the circulation, poliovirus from the gut, and enterovirus from the brain, leading to progressive and sometimes fatal outcomes.

Fig. 34.1 Defects in B-cell development can lead to humoral immune deficiency. Failure to generate a functional antibody receptor (μ , μ heavy-chain deficiency; λ_5 surrogate light-chain λ_5 , $\lambda 14.1$ deficiency) or to transmit signals through Bruton's tyrosine kinase (X-linked agammaglobulinemia (XLA)) can prevent or limit B-cell production. Failure to engage in proper cognate interactions with T cells (X-linked hyper-IgM syndrome (X-HIGM), CD40 deficiency) or disruptions in the genes that permit class switch recombination (activation-induced cytidine deaminase (AID), uracil-DNA glycosylase (UNG)) can prevent class switching and production of immunoglobulin G (IgG), IgA or IgE. A selective or generalized failure to progress from the immature B-cell stage to the plasma cell stage can lead to IgA deficiency (IgAD) or common variable immunodeficiency (CVID).

Because sinopulmonary infections are also commonly seen in normal infants and children, in allergic individuals, in smokers, and in patients with other diseases such as cystic fibrosis, the threshold for an extensive evaluation for immunodeficiency can be a matter of clinical judgment. However, two or more episodes of bacterial pneumonia within a 5-year period, unexplained bronchiectasis, *Haemophilus influenzae* meningitis in an older child or adult, chronic otitis media in an adult, recurrent intestinal infections and diarrhea due to *Giardia lamblia*, or a family history of immunodeficiency all warrant evaluation.

The purest forms of antibody deficiency result from mutations that allow VDJ rearrangement but prevent the expression or function of the pre-B-cell receptor. For example, a function-loss mutation of the μ heavy chain or components of the surrogate light chain (VpreB, $\lambda 14.1$ (λ_5)) will affect only the B-cell lineage. However, these rare immune deficiencies are the exception, because most of the diseases associated with primary antibody deficiency involve more than one cell lineage. For example, *X-linked agammaglobulinemia* (XLA) is the product of loss-of-function mutations in Bruton's tyrosine kinase (*BTK*), a key component of the BCR signal transduction pathway. *BTK* is also expressed in neutrophils, and under stressful conditions XLA patients have developed recurrent neutropenia. Patients with *X-linked hyper-IgM syndrome* (HIGM1) may also exhibit T-cell dysfunction, placing them at risk for infection with *Pneumocystis jiroveci*. Immune deficiency also appears to place patients at risk for autoimmunity, which is increased among patients with *IgA deficiency* (IgAD), *common variable immunodeficiency* (CVID), and *hyper-IgM syndrome*.

KEY CONCEPTS

HYPOGAMMAGLOBULINEMIA AND ANTIBODY DEFICIENCY

- >> The genetic mutations that underlie most primary antibody deficiencies tend to affect genes that play key roles in the regulation of lymphocyte differentiation, or in the generation of the antibody repertoire
- >> Clinically significant antibody deficiency is not synonymous with laboratory hypogammaglobulinemia
- >> Serum immunoglobulin concentrations vary widely with age
- >> Serum immunoglobulin levels vary with exposure to drugs (e.g., steroids), infectious agents, and other environmental stressors
- >> A complete absence of immunoglobulin G subclasses resulting from homozygous deletions of heavy-chain genes has been observed in healthy individuals
- >> Absence of a specific V_k gene segment has been associated with an increased risk of *Haemophilus influenzae* infection in spite of normal serum immunoglobulin levels

Clinical manifestations of the primary immunodeficiency will also be heavily influenced by the patient’s medical history. Patients with a delayed diagnosis or in situations wherein their infections have not been treated aggressively may suffer permanent damage to the respiratory or gastrointestinal mucosa, creating susceptibility to nontypable *H. influenzae*, staphylococci, and enteric bacteria as well.

PRINCIPLES OF DIAGNOSIS AND TREATMENT

DIAGNOSTIC TESTS AND THEIR INTERPRETATION

Laboratory testing for the diagnosis of immunodeficiency can be a time-intensive and expensive proposition. Table 34.2 illustrates four levels of testing complexity and when such testing might commonly be undertaken. In general, testing should be performed when the patient has a history of repeated infections that exceeds expectations for normal individuals, when an opportunistic pathogen or one of a low virulence is responsible for an infection, when a diagnosis of a disorder frequently associated with immunodeficiency has been made, or when a family history of immunodeficiency has been obtained.

Determination of serum immunoglobulin concentrations (IgM, IgG, and IgA), testing complement (50% hemolytic power of serum (CH₅₀) and complement components C3, and C4), a complete blood count

(CBC), and an erythrocyte sedimentation rate (ESR) are among the most cost-effective screening tests available. Lymphopenia is found most often in disorders that affect the production or function of T cells (Chapter 35), but can also occur in patients with CVID. Congenital absence of an individual complement component will result in total absence of measurable complement-mediated hemolysis (Chapter 20). The ESR is often, although not always, elevated in individuals with inflammatory disorders and can be useful in the evaluation of patients with a questionable or unclear history of recurrent or chronic infection.

KEY CONCEPTS

TEST FOR IMMUNE FUNCTION SHOULD BE PERFORMED

- >> When the patient’s history suggests a rate or severity of infection that exceeds normal expectations
- >> When the organism responsible for infection is of low virulence or is considered to be an opportunistic pathogen
- >> When there is a diagnosis of a genetic syndrome or disorder associated with immune deficiency either in the patient or in the patient’s family

Table 34.2 Laboratory diagnosis of primary antibody deficiency

Level	Test	Application (s)
I	Complete blood count with differential Complement (CH ₅₀ , C3, C4) Erythrocyte sedimentation rate Quantitative serum IgM, IgG, and IgA levels	Primary screening tests
II	B-cell functional evaluation Quantitative IgG subclasses Natural or commonly acquired antibodies (isohemagglutinins, rubella, rubeola, tetanus) Response to immunization T-cell-dependent antigens (tetanus) T-cell-independent antigens (unconjugated pneumococcal vaccine, unconjugated <i>Haemophilus influenzae</i> B vaccine)	Level I normal but history suggests antibody deficiency Better definition of a level I defect
III	Quantification of blood T- and B-cell subpopulations by immunofluoresence assays using monoclonal antibody markers T cells: CD3, CD4, CD8 B cells: CD19, CD20, CD21, Ig (μ, δ, κ, λ),	Panhypogammaglobulinemia or severely low IgM and IgA
IV	Disease-specific analysis Gene expression Gene sequencing	Gene-specific diagnosis Genetic counseling

Interpretation of the significance of the quantitative immunoglobulin determinations requires appreciation of age-related changes in immunoglobulin concentrations (Fig. 34.2).^{3–6} At the end of the second trimester of pregnancy, there is active transport of IgG across the placental barrier. At birth the infant's serum IgG concentration is typically 20–25% higher than that of the mother. Catabolism of maternal IgG coupled with the slow development of endogenous antibody function leads to a physiologic nadir of serum IgG in infants 4–6 months of age. In normal infants, this loss of maternal protection is often associated with the first appearance of otitis media or bronchitis. Thus, the onset of sinopulmonary infections within the first 3 months of age should also raise the index of suspicion for immunodeficiency in the mother. After age 6 months, maternally derived IgG has largely been lost, and IgG antibodies specific for diphtheria or tetanus become useful functional measures.

IgM is the first isotype to reach young adult levels, followed by total IgG and then IgA. This physiologic delay in the production of serum IgA can complicate the diagnosis of IgA deficiency in infants and young children. Serum immunoglobulin concentrations in healthy adults tend to remain remarkably constant, but can increase dramatically in response to infection and can decline in response to immunosuppressive agents, such as corticosteroid administration. With increasing age, serum immunoglobulin concentration may continue to rise.⁵ The physiologic significance of this increase in the elderly is unclear, although in some cases it reflects an accumulation of expanded B-cell clones or monoclonal gammopathies (Chapter 78).

The common laboratory practice of defining the lower range of normal for serum immunoglobulin levels as two standard deviations below

the age-adjusted mean carries with it the risk of falsely labeling otherwise normal patients immunodeficient. Immunoglobulin levels vary widely with environmental exposure and normal biologic variation is much broader than that defined by the mean of the population. Symptomatic patients with IgA deficiency may demonstrate normal total IgG levels, but have sufficient IgG₁ levels that mask deficiencies of IgG₂ and IgG₄. Patients with this compound immune deficiency may benefit from more aggressive therapy; thus quantitative measurements of all four IgG subclasses IgG₁, IgG₂, IgG₃, and IgG₄ can be useful in fully defining the extent of humoral immune deficiency. Among patients with borderline serum IgG levels, tests to evaluate the host's ability to produce functional specific antibody should be performed prior to making a decision to institute replacement therapy with human immunoglobulin, especially among patients receiving corticosteroids which can lower total IgG levels while preserving function.

The most commonly employed tests include measurement of isohemagglutinins (naturally occurring IgM antibodies to the polysaccharide antigens that define the ABO blood-type system on red blood cells), antibodies to polysaccharide antigens after immunization (e.g., Pneumovax) or unconjugated *H. influenzae* B vaccine, and antibody responses to protein antigens after immunization (e.g., tetanus or diphtheria toxoids). IgM is made by the newborn, and most infants can generate isohemagglutinins, making determination of anti-A and anti-B titers a useful measurement of B-cell function even in infants. In older children and adults, isohemagglutinin titers of less than 1:8 are considered significant.⁷ Serum for specific antibody titers should be obtained before and 3–4 weeks after immunization. The paired sera should be assayed simultaneously to avoid confusion that may result from

Fig. 34.2 Age-related changes in the serum concentration of immunoglobulins. Shown are average serum immunoglobulin concentrations of the major isotypes as a function of age.^{5, 6}

single-tube dilution differences at the time the assay is performed. As a general rule, a high baseline titer or a fourfold or greater rise in a specific titer in individuals with a low baseline titer confirms that a specific humoral response is intact. One caveat: responses to immunization with unconjugated pneumococcal polysaccharide vaccines are not reliable measures of age-appropriate B-cell function until after the age of 2 years. The development of conjugated polysaccharide vaccines complicates analysis for children who have received such a vaccine, but information can still be gleaned from study of responses to polysaccharide antigens present only in multivalent unconjugated vaccines.

Disorders of the gastrointestinal tract or kidneys that result in protein loss through the stool or urine precipitate the selective loss of IgG because of its relatively low molecular weight and slow turnover compared with other isotypes.

An elevated IgE level may support a suspicion of allergy as an underlying explanation of sinopulmonary symptoms. Serum IgE concentrations are often elevated in patients with IgA deficiency. Extreme elevations of IgE suggest the *hyper-IgE syndrome*.

Enumeration of B cells and of T cells should be performed for any individual who has severe panhypogammaglobulinemia. The most widely used method of demonstrating B cells relies on immunofluorescent labeling of surface CD19, which is restricted in expression to mature B cells. Because an infant may have serum IgG of maternal origin for the first several months of life, the determination of the number of circulating B cells is the single most useful test in making the presumptive diagnosis of XLA, a disorder in which pre-B cells in the bone marrow fail to develop to cells of mature phenotype. Absence of circulating B cells also characterizes the *immunodeficiency associated with thymoma* in adults, whereas adults with *chronic lymphocytic leukemia* may have hypogammaglobulinemia with an overabundance of circulating B cells that typically express CD5, a common T-cell antigen.

HIGM1 represents the product of a loss-of-function mutation of the *CD154 (CD40L)* gene. CD154, a surface antigen found on activated T cells, binds CD40 on B cells to facilitate class switching, survival, and proliferation (Chapter 9). A fluorescent labeled CD40 fusion protein can be used to evaluate the expression of functional CD154 on T cells by flow cytometry. XLA reflects a loss-of-function mutation of *BTK*. As typical for previously lethal X-linked disorders, a high percentage of cases represent new mutations. Confirmation of the diagnosis, carrier detection, and prenatal diagnosis often depend on a molecular or sequence analysis of the gene in question.

REPLACEMENT THERAPY WITH HUMAN IMMUNOGLOBULIN

There are a number of commercial preparations of human immunoglobulin that are approved by the Food and Drug Administration and available in the USA (Chapter 85). No commercial preparations in this country are available to supplement IgM or IgA. All commercial human immunoglobulin preparations are effective in treating patients with immunodeficiency disorders. Clinically relevant differences relate to the route of administration, which can be by intravenous or subcutaneous means, to the method of stabilization and storage, and to quantities of contaminating serum IgA in the preparations. Low IgA content is important for those rare individuals with immunodeficiency and absent IgA who can manufacture IgG or IgE antibodies directed against IgA

and are thus at risk for anaphylactic reactions upon infusion of IgA-containing blood products.⁸

Immunoglobulin replacement therapy is not indicated for patients whose immune deficiency is limited to the selective absence of IgA. Indeed, selective IgA deficiency has long been viewed as a relative contraindication for immunoglobulin replacement because of the risk of anaphylaxis upon receipt of IgA-containing products, even though such reactions are extremely rare. Immunoglobulin replacement therapy has been found to be beneficial in patients with a combined deficit of IgA and IgG subclasses who exhibit impaired antibody responses to carbohydrate antigens.

The goal of immunoglobulin replacement is to provide sufficient concentrations of functional antibodies to prevent disease, not to achieve a target IgG level in the serum. Specific approaches to and protocols for immunoglobulin replacement therapy have been extensively evaluated by the American Academy of Allergy, Asthma, and Immunology⁹ and are described in detail in Chapter 85. The only indication for immunoglobulin replacement in a patient with immunodeficiency is severe impairment of the ability to produce functional antibody. Such impairment exists in primary immunodeficiency diseases associated with low levels of all five isotypes of immunoglobulin, such as XLA, CVID, HIGM, and *severe combined immunodeficiency* (Chapter 35). Patients with normal or near-normal levels of IgG but a documented inability to produce specific antibodies after immunization are also candidates for intravenous immunoglobulin therapy if they suffer with significant infections. This is true for certain cases of IgG subclass deficiency such as those associated with compound IgA, IgG₂, and IgG₄ deficiency, for boys with Wiskott–Aldrich syndrome, and for patients with ataxia-telangiectasia. Since most patients with transient hypogammaglobulinemia of infancy can produce normal amounts of specific antibodies after immunization despite having a low total serum IgG, they are not usually candidates for immunoglobulin replacement. Intravenous immunoglobulin is unlikely to be beneficial in selective IgA deficiency or selective IgG₄ deficiency.⁹

X-LINKED AGAMMAGLOBULINEMIA

DIAGNOSIS

XLA, also known as Bruton agammaglobulinemia, is the prototypic humoral immunodeficiency.¹⁰ Function-loss mutations in *BTK* lead to a block in B-cell maturation, a near-total absence of B cells in the periphery, and panhypogammaglobulinemia. Due to the transplacental transfer of maternal immunoglobulin, affected boys typically do not begin to suffer recurrent pyogenic infections until after age 6 months. The normal delay in endogenous immunoglobulin production and the presence of maternal IgG require that testing of infants known or suspected to have XLA should begin with examination of the number of B cells in the blood. Deficient expression of BTK protein can be detected by flow cytometry, a technique that can also be used for carrier detection. For those cases where protein is present but the phenotype suggests XLA, analysis of the *BTK* gene at the nucleotide level remains the definitive diagnostic procedure. A large number of different mutations have been found and collected into a disease-specific database known as BTKbase (<http://bioinf.uta.fi/BTKbase>). As with most X-linked lethal diseases, approximately one-third of sporadic cases are due to *de novo* mutations

and diagnosis may require individual mutation analysis. There can be significant variation in the manifestations of the disease in any given family member, thus a paucity of symptoms should not prevent diagnostic evaluation.

CLINICAL MANIFESTATIONS

Although patients begin to suffer recurrent infections by age 1 year, with antibiotics and good hygiene it is not uncommon to delay suspicion of the diagnosis well into mid-childhood. Indeed, diagnoses have been made in older adults, including aged male relatives of affected probands. Recurrent upper and lower respiratory tract infections are common, including otitis media, sinusitis, bronchitis, and pneumonia. Untreated, these infections may lead to bronchiectasis (Fig. 34.3), pulmonary failure, and death at an early age. The infections are typically due to pyogenic encapsulated bacteria, including *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Staphylococcus aureus*, and *Pseudomonas* species. Diarrhea due to *Giardia lamblia* is also common, although less so than in CVID. Systemic infections include bacterial sepsis, meningitis, osteomyelitis, and septic arthritis. *Mycoplasma* and *Chlamydia* infections of the urogenital tract may lead to epididymitis, prostatitis, and urethral strictures. Skin infections include cellulitis, boils, and impetigo.

Fig. 34.3 A computed tomographic scan with contrast demonstrates bronchiectasis, bronchitis, and emphysema in the lungs of a 36-year-old man with X-linked agammaglobulinemia (XLA). Due to a left lower-lobe lobectomy, the mediastinum has shifted to the left. As a result of bronchiectatic scarring, the diameter of the bronchi in the right lung is greater than the diameter of the corresponding blood vessels, and the bronchi remain dilated in the periphery. Bronchial plugs can be seen filling some of the bronchi on the right. Finally, due to emphysema, the right upper lobe demonstrates greater radiolucency. In addition to suffering from XLA, this patient has a 30-pack-year history of smoking, which has exacerbated his clinical condition.

Although patients with XLA can resolve most viral infections, they are unusually sensitive to infections with enteroviruses, including echovirus, coxsackievirus, and poliovirus. Patients with XLA can develop paralytic poliomyelitis after vaccination with live virus. Echovirus and coxsackievirus infections may involve multiple organs, with the patients going on to develop chronic meningoencephalitis, dermatomyositis, and/or hepatitis.

Untreated patients often complain of arthritis affecting the large joints. This appears to have an infectious etiology, because the arthritis typically resolves with immunoglobulin replacement therapy. Enterovirus and *Mycoplasma* have been identified in the affected joints of these patients.

Infections with opportunistic organisms, such as tuberculosis, histoplasmosis and *Pneumocystis jiroveci*, and malignancies are rare, likely reflecting intact cell-mediated immunity.

ORIGIN AND PATHOGENESIS

BTK belongs to a subfamily of the Src cytoplasmic protein-tyrosine kinases. It includes five distinct domains: a pleckstrin homology domain (PH), a Tec homology (TH) domain, a Src homology 3 (SH3) domain, a SH2 domain, and a SH1 domain. The latter is also referred to as the catalytic, or kinase, domain. BTK is phosphorylated following activation of the B-cell receptor (BCR). Its precise role in the BCR activation pathway remains elusive; however it is now clear that BTK plays a critical role in the proliferation, development, differentiation, survival, and apoptosis of B-lineage cells. Individuals with XLA begin with normal numbers of early B-lineage progenitors in their bone marrow. These B-cell progenitors express the expected markers of B differentiation, including terminal deoxyribonucleotide transferase (TdT), CD19, and CD10. There is, however, a relative deficiency of cells containing cytoplasmic μ heavy chains in the bone marrow. Development of cells beyond the pre-B stage is even more severely impaired. Those cells that make it through the gauntlet can produce antigen-specific antibodies. Although in low numbers, the presence of these B cells in lymphoid tissues enables XLA patients to express endogenous immunoglobulin, class switch, and even suffer allergic reactions. Hypogammaglobulinemia thus appears to result from inadequate rather than absent B-cell numbers.

Patients have been described with an X-linked recessive form of agammaglobulinemia that is associated with growth hormone deficiency. Genetic analysis of the *BTk* gene in one such patient identified a frameshift mutation leading to a premature stop codon and the loss of carboxy-terminal amino acids.¹¹

TREATMENT AND PROGNOSIS

The primary goal of therapy is to prevent damage to the lungs. Human immunoglobulin replacement therapy should be started as soon as the diagnosis is made. Patients treated with quantities (0.4–0.6 g/kg every 3–4 weeks) of intravenous immunoglobulin sufficient to achieve trough levels of >500 mg/dl suffer few lower respiratory tract infections. However, these patients remain at risk for viral infections, including enteroviral meningoencephalitis. Since mucosal immunoglobulin cannot be replaced, the patients also remain at risk for recurrent upper respiratory infections, which may require prophylactic antibiotic therapy. Immunoglobulin-treated patients may lead normal lives without concern about exposure to infectious agents in childcare settings or classrooms. Immunizations of any type are unnecessary because the monthly

replacement therapy will provide passive specific antibody. Since patients are unable to mount antibody responses and vaccines carry some risk of untoward side effects, they are relatively contraindicated.

An XLA patient who develops symptoms of enteroviral central nervous system or neuromuscular infection should have appropriate culture of the involved organ system. Cerebrospinal fluid culture and analysis for cells and protein should be performed and a muscle biopsy for culture should be considered if virus is not recoverable from stool or cerebrospinal fluid. Although there are no clear guidelines for managing patients with chronic enteroviral infections, immunoglobulin therapy should be accelerated for at least several weeks and higher doses maintained until symptoms cease and the virus can no longer be detected.

AUTOSOMAL AGAMMAGLOBULINEMIA

Mutations in genes whose products are required for B-cell differentiation can produce a selective block in B-cell development nearly indistinguishable from XLA.¹² Expression of the pre-B-cell receptor is a key step in the maturation of the pre-B cell. Function-loss mutations in any one of the genes that code for components of the pre-BCR can inhibit pre-B-cell development, blocking B-cell production. An absence of B cells has been reported for patients with function-loss mutations in both alleles of the μ heavy chain region (μ_0), λ -like surrogate light chain (IGLL1), or immunoglobulin-associated beta chain (Ig β). Patients with homozygous mutations in the adaptor B-cell linker protein (BLNK), a key component of the signaling pathway for the pre-BCR, exhibit an absence of B cells and agammaglobulinemia. An absence of B cells has also been reported in a patient with a truncation of LRRC8, a gene of unknown function that is expressed in progenitor B-cell patients. In this case, the patient was heterozygous for the molecular defect. Diagnosis in each of these cases requires gene mutation analysis. Treatment follows the same guidelines given for XLA.

HYPER-IGM SYNDROME

DIAGNOSIS

Patients with the hyper-IgM syndrome exhibit markedly reduced serum concentrations of IgG, IgA, and IgE with normal to elevated levels of IgM and normal numbers of circulating B cells.¹³ The altered distribution of immunoglobulin isotypes reflects a block in the ability of B lymphocytes to switch from IgM to the other isotypes. Increased IgM reflects polyclonal expansion of IgM synthesis in response to infection. HIGM patients suffer the same infections with encapsulated bacteria common to all patients with antibody deficiency. The HIGM phenotype can be either inherited or acquired. Both X-linked and autosomal recessive forms of the disease have been identified. HIGM can also develop in association with neoplasia¹⁴ or congenital rubella.

Hyper-IgM syndrome type 1

Class switch recombination is a multistep process that requires exquisite coordination between the B cell and its cognate helper T cell. A key step in the initiation of the process is the binding of constitutively expressed

CD40 on the B cell to its ligand, CD40L (CD154), which is expressed on activated T cells. The most common X form of the disease, HIGM1, results from loss-of-function mutations in *CD154*.

Hyper-IgM syndrome type 2 (HIGM2)

Activation-induced cytidine deaminase (AID), a member of the cytidine deaminase family, is required for class switch recombination between immunoglobulin H-chain constant domains and for somatic hypermutation of the immunoglobulin V domains (Chapter 4). AID is expressed only in activated B cells. Function-loss mutations on both *AID* alleles yield a hyper-IgM syndrome.

Hyper-IgM syndrome type 3 (HIGM3)

The cognate partner for CD40L (CD154) is the CD40 gene, which is located on an autosome (20q12-q13.2). HIGM3 patients with function-loss mutations on both alleles of the *CD40* gene present with a phenotype indistinguishable from HIGM1, with the exception that, as an autosomal recessive condition, females and males are equivalently affected.

Hyper-IgM syndrome type 4 (HIGM4)

Patients presenting with an HIGM-like phenotype, but lacking demonstrable mutations in genes previously associated with HIGM, such as *CD40*, *CD154*, *NEMO*, *AID*, and *UNG*, have been grouped by some immunologists into a category termed HIGM4.¹⁵

Hyper-IgM syndrome type 5 (HIGM5)

AID acts by deaminating cytidine nucleotides in DNA, leaving a uracil nucleotide in its place. Uracil-DNA glycosylase (UNG) can remove the uracil, permitting normal or error-prone repair. Patients with function-loss mutations on both alleles of the *UNG* gene have presented with a history of bacterial infections, hyperplasia, increased serum IgM levels, and low IgG and IgA.

Hyper-IgM immunodeficiency, X-linked, with ectodermal dysplasia, hypohidrotic (XHM-ED)

The nuclear factor kappaB (NF- κ B) essential modulator (NEMO) plays a key role in the CD40 signal transduction pathway. *NEMO* is located on the X-chromosome and its protein product also influences ectodermal development. In addition to hypogammaglobulinemia, XHM-ED patients with mutations in *NEMO* may also present with conical teeth, an absence of eccrine sweat glands, and a paucity of hair follicles.

CLINICAL MANIFESTATIONS

CD40–CD154 axis (HIGM1, HIGM3, and XHM-ED)

The majority of patients with HIGM have inherited disruptions in the CD40–CD154 axis. The spectrum of disease in these patients has been well characterized. Recurrent upper and lower respiratory tract infections

are the most common clinical complaint. Patients may also exhibit recurrent neutropenia with oral ulcers and perirectal abscesses and opportunistic infections with *Pneumocystis jiroveci*, *Toxoplasma gondii*, or *Cryptosporidium* cholangitis. Autoimmunity is observed in approximately 20% of patients, and lymph nodes and spleen are deprived of germinal centers. These features signal a compromise in cell-mediated immunity as well as the characteristic flaw in antibody production.

Without prophylaxis, one-third of patients develop *P. jiroveci* (previously *carinii*) pneumonia (PCP), which can be the presenting complaint in affected infants. These patients are also at risk for serious infections with cytomegalovirus (CMV), adenovirus, *Cryptococcus neoformans*, or mycobacteria.

Chronic diarrhea occurs in more than half of the patients. Organisms include *Cryptosporidium*, *Giardia lamblia*, *Salmonella*, and *Entamoeba histolytica*. One-quarter may require total parenteral nutrition due to diarrhea or to perirectal abscesses. Oral ulcers, gingivitis, and perirectal ulcers are associated with neutropenia, which may occur chronically or intermittently in up to two-thirds of the patients. One-fifth of the patients develop sclerosing cholangitis that can lead to hepatic failure. Cryptosporidiosis is present in half of these patients. Infections with hepatitis B and C are associated with exposure to blood products.

Although originally distinguished by the high level of serum IgM, IgM levels are often normal in affected individuals. IgG is low in all patients. IgA and IgE are usually low, but can be normal or even elevated in one-tenth of the population. B- and T-cell counts are within the normal range in more than 90% of the patients, and depressed in the rest.

Lymphoid hyperplasia is a common finding in CD40–CD154 axis patients with active infections. Individual nodes may become extremely large and some patients develop splenomegaly. Hilar adenopathy causes a diagnostic dilemma, as the risk of lymphoma is increased in HIGM. Although the lymphoid tissue is usually histologically abnormal, reactive processes are far more common than malignancy. Plasma cells may be abundant or sparse. Primary follicles are poorly developed. The most characteristic abnormality is the absence of germinal centers. Nodular lymphoid hyperplasia of the intestine is frequent and may be accompanied by malabsorption and protein-losing enteropathy. Diffuse lymphoid infiltration of various organs and tissues may also occur.

AID–UNG axis (HIGM2 and HIGM5)

Infected AID–UNG-deficient patients may present with giant germinal centers filled with highly proliferating B cells, presumably due to intense antigen stimulation. Approximately 25% of patients present with evidence of autoimmunity, which may manifest as hemolytic anemia, thrombocytopenia, or autoimmune hepatitis. Autoantibodies in these patients are of the IgM isotype. Unlike deficiencies of the CD40–CD154 axis, cell-mediated immunity is unaffected.

ORIGIN AND PATHOGENESIS

CD40–CD154 axis (HIGM1, HIGM3, and XHM-ED)

CD154 is a type II transmembrane protein belonging to the tumor necrosis factor (TNF) family that is predominantly expressed on mature, activated CD4 T cells. Its expression peaks at 6–8 hours post-activation and then falls to resting levels by 24–48 hours. CD154 is also expressed

on CD4 thymocytes, activated CD8 T cells, natural killer cells, monocytes, basophils, mast cells, activated eosinophils, and activated platelets. Newborn T cells are deficient in CD154 expression, although they can be induced to express the antigen if strongly stimulated.

CD40 is a member of the TNF receptor superfamily. It is constitutively expressed on pro-B, pre-B, and mature B cells. CD40 is also expressed on interdigitating cells, follicular dendritic cells, thymic epithelial cells, monocytes, platelets, and some carcinomas.

Engagement of CD40 on the B-cell surface with activated T cells that express CD154 and Fas ligand (CD95L or FasL) leads to the upregulation of Fas (CD95) on the B cell. If the B cell has concomitantly bound its cognate antigen and engaged the B-cell receptor signaling pathway, it becomes resistant to Fas-mediated apoptosis and expresses CD80/CD86 on the cell surface. The activated B cell can then engage CD28 on the T-cell surface and trigger the T cell to secrete its cytokines. If the B cell fails to engage its BCR, the Fas pathway predominates and the B cell is eliminated. With proper activation of the CD40–CD154 pathway, exposure to interleukin-2 (IL-2) and IL-10 induces production of IgM, IgG₁, and IgA; exposure to IL-4 induces production of IgG₄ and IgE. This change in immunoglobulin isotype reflects both induction of switching and the enhanced survival and proliferation of the B cell. In the absence of CD154, B cells can express IgM, but have difficulty switching and are likely to undergo apoptosis rather than proliferate in response to antigen.

CD40–CD154 interactions between CD154⁺ T cells and CD40⁺ macrophages lead to enhanced production of IL-12, which then stimulates T cells to release interferon- γ . Activation of this pathway appears necessary for the defense against *Pneumocystis jiroveci* and other opportunistic organisms. Its absence likely contributes to cell-mediated immune deficiency.

TREATMENT AND PROGNOSIS

The availability of human immunoglobulin replacement therapy has greatly improved the quality of life in HIGM. Adequate replacement can result in the reduction of serum IgM concentrations, prevention of infections with encapsulated bacteria, resumption of growth, and the gradual resolution of splenomegaly and lymphoid hyperplasia. Neutropenia persists but may be clinically silent.

However, in spite of the improvement granted by immunoglobulin replacement, the prognosis of patients with defects in the CD40–CD154 axis remains guarded. Among the patients in the European Registry,¹⁶ one-quarter of HIGM1 patients died before the age of 25. These deaths were primarily the result of opportunistic infections, including PCP, cholangitis, CMV, mycobacterial infections, and cirrhosis secondary to hepatitis. Prophylaxis with trimethoprim-sulfamethoxazole can significantly reduce the risk of PCP. There is also an increased incidence of carcinomas of the liver, pancreas, and biliary tree, and perirectal abscesses can prove difficult to manage. Regular monitoring of gastrointestinal manifestations and management of neutropenia are mandatory. Bone marrow transplantation is a viable option for patients who fail to respond to supportive therapy.

IGA DEFICIENCY

Selective IgAD, selective IgG subclass deficiencies, CVID, and a syndrome of recurrent sinopulmonary infections (RESPI) with normal serum immunoglobulin levels appear to share an overlapping set of gene

defects.^{1,17–20} Clinically, these disorders are marked by an increased susceptibility to sinopulmonary infections with encapsulated bacteria. IgAD and CVID feature similar B-cell differentiation arrests, but differ in the extent of immunoglobulin deficits. The correlation between serum immunoglobulin levels and severity of infection is not absolute. Virtually agammaglobulinemic patients may suffer with only occasional sinusitis, whereas patients with near-normal serum immunoglobulin levels may present with recurrent pneumonia and bronchiectasis.

DIAGNOSIS

Approximately 1 in 600 individuals of European ancestry are unable to produce detectable quantities of IgA1 and IgA2, making selective IgAD the most frequently recognized primary immunodeficiency in the Americas, Australia, and Europe. The diagnosis is dependent on the sensitivity of the laboratory measurement. The clinical laboratory typically reports serum IgA levels of less than 7 mg/dl, the concentration below which nephelometry becomes unreliable.

Uncomplicated patients with IgAD have normal serum levels of IgM and normal or elevated levels of IgG, and demonstrate normal cell-mediated immunity. A minority of patients may demonstrate additional evidence of immune dysfunction, with inability to generate appropriate IgG₂ anti-carbohydrate antibodies, frank IgG subclass deficiencies, or evidence of impairment of T-cell function. Patients with IgA serum levels that fall more than two standard deviations below the mean serum level for their age are considered to have partial IgA deficiency. These patients can also suffer from recurrent infections.

CLINICAL MANIFESTATIONS

The likelihood that an IgA-deficient individual who was identified serendipitously will require medical attention is difficult to assess because most studies in the literature reflect patients who were ascertained as a result of clinical symptoms. Among IgAD patients referred to immunology clinics, more than 85% present with recurrent infections, typically with encapsulated bacteria such as *Haemophilus influenzae* and *Streptococcus pneumoniae*. Among affected children, symptoms may begin in the first year of life, although the physiologic lag in serum IgA may delay the diagnosis until after the age of 2. In some patients, respiratory infections disappear with maturity. In others, infections may persist throughout adult life. Rarely IgAD patients experience recurrent bronchitis, pneumonia, and even bronchiectasis. These more severely afflicted patients often exhibit IgG₂ and IgG₄ subclass deficiencies, as well. Chronic intermittent diarrhea due to *Giardia lamblia* is a common complaint, although there are indications that this may track more closely with related deficits in IgG function. Systemic infections such as viral hepatitis, meningoen- cephalitis, and septicemia may also occur. Some symptomatic patients have elevated IgE levels, which can introduce an allergic or asthmatic component to respiratory dysfunction. The rise in IgE has been explained as a compensatory response to the absence of IgA. This appears to be a double-edged sword, because up to 20% of patients complain of allergic rhinitis, conjunctivitis, urticaria, and atopic eczema. Allergic reactions may be enhanced due to the lack of IgA blocking antibodies in the serum, and unusually severe asthma has also been associated with IgAD.

IgA-deficient patients rarely produce IgG or IgE anti-IgA antibodies. These uncommon patients are at risk for adverse reactions following transfusion with blood products, as mentioned previously, plasma from

normal donors, or from some preparations for immunoglobulin replacement therapy which, of course, contain IgA. Patients with high anti-IgA levels (greater than 1:1000) typically have potent antibodies directed against all IgAs. These patients are at risk for severe anaphylaxis. Patients with low anti-IgA antibody titers (less than 1:256) are often multiparous or multi-transfused patients. These patients rarely demonstrate severe anaphylaxis after infusion with plasma or blood products, but do present with hives and rashes. Serum complement typically falls as a result of this type of reaction.

IgAD patients often develop autoimmune diseases. These include juvenile rheumatoid arthritis, systemic lupus erythematosus, Addison's disease, chronic nephritis, dermatomyositis, Evans syndrome, isolated hemolytic anemia, isolated idiopathic thrombocytopenic purpura, insulin-dependent diabetes mellitus, pulmonary hemosiderosis, sarcoidosis, Sjögren's syndrome, Henoch-Schönlein syndrome or hemorrhagic purpura, and thyroiditis. Gastrointestinal disorders include celiac disease, inflammatory bowel disease, intestinal disaccharidase deficiency, lactase deficiency, pancreatic insufficiency, and pernicious anemia. Hepatobiliary disorders include chronic active hepatitis, cholelithiasis, lupoid hepatitis, and primary biliary cirrhosis. Skin disorders include pyoderma gangrenosum, perinychia, and vitiligo. It is unclear whether this autoimmune diathesis is the end result of recurrent infections, the product of recurrent insult by antigens that would otherwise be cleared by IgA, or whether the underlying deficit that leads to IgAD also increases the risk of developing an autoimmune disorder. For example, autoimmune disorders such as insulin-dependent diabetes mellitus and celiac disease are associated with the same major histocompatibility complex (MHC) haplotypes (Chapter 5) as IgAD and CVID.

IgAD is associated with an increased risk for the development of malignancies,²¹ including gastric and colonic adenocarcinoma and acute lymphoblastic leukemia. Hepatoma, lymphosarcoma, melanoma, multiple myeloma, ovarian carcinoma, squamous cell carcinoma, and malignant thymoma have also been reported. Cervical and bronchial lymphadenopathy can be found in IgAD patients who suffer from recurrent sinopulmonary infections. Patients with chronic gastrointestinal infections may demonstrate a nodular lymphoid hyperplasia of the small intestine that can lead to intestinal obstruction. Histologic evaluation reveals active B-lymphocyte proliferation in the germinal centers of the Peyer's patches. These "constipated" lymph nodes have been mistaken for lymphoma. In some cases, it is possible to attribute the increased risk of malignancy to the lack of protection against ingested carcinogens. In others, the simultaneous presence of IgAD and malignancy may simply reflect the high prevalence of IgAD in the Caucasian population.

ORIGIN AND PATHOGENESIS

IgAD, selective IgG subclass deficiencies, and CVID are diseases that are defined by a quantitative phenotype, a paucity of serum immunoglobulins of a given isotype in spite of the presence in the blood of B lymphocytes bearing the missing isotypes. By definition, the fundamental defect involves the failure of B lymphocytes bearing a given isotype to differentiate into plasma cells. These diseases appear to represent a common endpoint for multiple pathogenic processes. All three phenotypes may be acquired and many of the recognized precipitating causes, such as phenytoin, are the same (Table 34.3).

IgA deficiency is associated with MHC haplotypes that are more common in European populations than in the peoples of sub-Saharan

African and East Asia. In the USA, the prevalence of IgAD among African-Americans is one-twentieth of that observed among Americans of European descent and in Japan the incidence is approximately 1 in 18 500. Function-loss mutations in a variety of non-MHC genes have now been defined in families with IgA-deficient/CVID members. These include the genes for ICOS, an immune co-stimulator molecule used by T cells to activate B cells in germinal centers, BAFFR and transmembrane activator and calcium modulator and cyclophilin ligand interactor (TACI), the receptors for B-cell-activating factor (BAFF), and CD19, the B-cell co-stimulatory receptor. Remarkably, several individuals with TACI mutations had also inherited MHC haplotypes associated with the disease, suggesting a complex etiology for the disorder.²²

TREATMENT AND PROGNOSIS

Most individuals with IgAD suffer respiratory infections no more frequently than the average individual and thus require no special treatment. All individuals with IgA deficiency should be warned of the risk of serious transfusion reactions caused by antibodies to IgA. Wearing a medical alert bracelet is recommended. Should transfusion be necessary, the ideal donors are other individuals with IgAD. Washed erythrocytes are safer than whole blood.

Patients with selective IgA deficiency who suffer from clinically significant, recurrent upper respiratory infections often respond to prophylactic antibiotics. Treatment of allergy in those patients with a

compensatory increase in IgE is helpful. Patients who present with combined IgA and IgG subclass deficiencies may require immunoglobulin replacement.

■ COMMON VARIABLE IMMUNODEFICIENCY ■

DIAGNOSIS

The diagnostic category of CVID includes a heterogeneous group of patients, mostly adults, who exhibit deficient production of all the different classes of antibodies. These patients typically have normal numbers of B lymphocytes in their blood that are clonally diverse, but phenotypically immature. B lymphocytes in CVID patients are able to recognize antigens and respond with proliferation, but they are impaired in their ability to become memory B cells and mature plasma cells. In infected patients, abortive differentiation can lead to massive B-lymphocyte hyperplasia, splenomegaly and intestinal lymphoid hyperplasia.

With an estimated prevalence of 1 in 25 000, CVID is the most prevalent human primary immunodeficiency requiring medical attention.²³ Men and women are equally affected. As with IgAD, the prevalence among African-Americans is one-twentieth that of Americans of European descent. Some patients present during childhood, but most are diagnosed in the third decade of life. The typical patient reports a normal pattern of recurrent otitis media as an infant and toddler that resolved in childhood. During adolescence, respiratory infections recur and steadily increase in frequency. Recurrent pneumonia as a young or middle-aged adult is often the precipitating complaint that brings the patient to the attention of the clinical immunologist. Although CVID thus appears to be an acquired disorder, family studies have clearly documented that susceptibility for the disease can be inherited and the manifestations of the disorder may change with time. Transitions within the spectrum of normal serum immunoglobulin concentrations to IgA deficiency to IgA deficiency with IgG subclass deficits to frank CVID have been documented in both sporadic and familial cases.²

Common variable immunodeficiency is a diagnostic category of primary immunodeficiencies that includes a number of immune disorders. Most CVID patients of northern European descent exhibit a distinctive phenotype characterized by a broad deficiency of immunoglobulin isotypes in spite of the presence of normal numbers of surface immunoglobulin-bearing B-cell precursors in the peripheral blood. Almost all of these patients are IgA-deficient and by definition demonstrate total serum IgG levels of less than 500 mg/dl. Some IgG subclasses are more affected than others, with the sequential order of involvement being IgG₄ > IgG₂ > IgG₁ > IgG₃. Most patients are also deficient in IgM and IgE. This pattern is common to patients with specific MHC susceptibility haplotypes as well as to those who have inherited function-loss mutations in the genes for ICOS, BAFFR, and TACI.

Uncomplicated patients demonstrate normal cell-mediated immunity, but a minority of patients may have evidence of T-cell dysfunction as well as other hematopoietic cell types. In some cases, B-cell numbers are reduced, although not to the extent exhibited by disorders of pre-BCR formation or signaling, as discussed in the sections on XLA and autosomal agammaglobulinemia or in the agammaglobulinemia associated with thymoma with pure red cell aplasia.

IgAD and CVID have been associated with congenital infection with rubella virus, cytomegalovirus, and *Toxoplasma gondii*. The administration of certain drugs has also been linked to a depression in serum immunoglobulin levels. Up to 20% of patients treated with phenytoin for idiopathic epilepsy suffer a mild decrease in serum IgA levels, and a minority may progress to a CVID-like phenotype. Medications used for the treatment of rheumatoid arthritis and inflammatory bowel disease can also decrease production of antibody. Persistence of antibody deficiency usually requires continued administration of the drug or continued infection with the virus or parasite. Recovery of immunoglobulin production may take months or years.

CLINICAL MANIFESTATIONS

The clinical manifestations of CVID are similar but more severe than the ones seen in IgAD. Respiratory symptoms often begin with recurrent sinusitis, otitis media, and mild bronchitis, which are typically due to encapsulated bacteria such as *Haemophilus influenzae* and *Streptococcus pneumoniae*. The frequency and severity of the upper respiratory infections worsen in the young adult and lower respiratory infections such as pneumonia become common. Apparently asymptomatic, untreated patients may suffer recurrent subclinical pulmonary infections that can lead to irreversible chronic lung damage with bronchiectasis, unilateral hyperlucent lung, emphysema, and cor pulmonale. With damage to pulmonary mucosa, the spectrum of bacterial pathogens broadens to include *Pseudomonas aeruginosa* and *Staphylococcus aureus*. Recurrent skin infections or erythroderma can be presenting complaints. The pathogenesis of these dermatologic manifestations remains unclear.

Intermittent or chronic diarrhea due to *Giardia lamblia* is a common complaint. Some unfortunate patients develop a malabsorption syndrome that resembles celiac sprue but is unresponsive to the avoidance of gluten (Fig. 34.4). Although allergic disorders are rare in CVID, antigen-specific IgE can be produced in sufficient quantities to enable anaphylactic reactions. Untreated patients often complain of an asymmetrical, oligoarticular arthritis which in some cases reflects infections with encapsulated organisms or with *Mycoplasma* species and thus requires antibiotic therapy. The arthritis typically responds to immunoglobulin replacement therapy.

CVID patients are often anergic, but only a minority suffer infections characteristic of cell-mediated immune dysfunction, such as mycobacteria, *Pneumocystis jiroveci*, and fungi. CD8 T-cell numbers may be depressed in such patients. Most viral infections are cleared normally. Exceptions include enteroviral infections, including meningoencephalitis, as well as hepatitis B and C, which can progress to a fatal chronic active hepatitis. Lack of humoral immunity enhances susceptibility to viral reactivation. Untreated patients often complain of recurrent herpes zoster infections (shingles).

Autoimmune diseases are common in CVID and include pernicious anemia, autoimmune neutropenia, Graves disease, hypothyroidism, rheumatoid arthritis, systemic lupus erythematosus, and Sjögren syndrome. Coombs-positive hemolytic anemia with idiopathic thrombocytopenic purpura, a combination known as Evans syndrome, may predate the diagnosis of CVID.

A sarcoidosis-like syndrome, characterized by noncaseating granulomas in the lung, lymph nodes, skin, bone marrow, and liver, is more common in African-Americans.²⁴ Occasionally the granulomas result from mycobacterial and fungal infections. In the majority of cases, the cause remains unclear and the granulomas resolve spontaneously.

Fig. 34.4 Hypogammaglobulinemic sprue in a 41-year-old white male with common variable immunodeficiency (CVID) and insulin-dependent diabetes mellitus. The patient suffered from intractable diarrhea. Shown is a hematoxylin and eosin stain of a duodenal biopsy obtained by endoscopy. The villi are blunted and there is a marked increase in intraepithelial lymphocytes. However, unlike typical celiac disease, the villi are not completely blunted and few plasma cells are seen. The patient is homozygous for the human leukocyte antigen (HLA)-B8,-DR3 haplotype. Although the patient failed to respond to a gluten-free diet, the diarrhea resolved with corticosteroid therapy.

The development of a constellation of pulmonary abnormalities that includes granulomatous and lymphoproliferative (lymphocytic interstitial pneumonia, follicular bronchiolitis, and lymphoid hyperplasia) histopathologic patterns, termed granulomatous-lymphocytic interstitial lung disease (GLILD),²⁵ can be an ominous sign. These patients appear more likely to develop granulomatous liver disease, autoimmune hemolytic anemia, lymphoproliferative disease, and progressive pulmonary disease. In one study,²⁵ median survival was reduced by more than 50%.

There is an increased risk for the development of gastrointestinal and lymphoid malignancies, especially non-Hodgkin's lymphomas. Confounding the diagnosis of malignancy is the patient's propensity to develop benign lymphoproliferative disorders. Lymphadenopathy, splenomegaly, or both are common in untreated patients. The lymph node architecture is usually preserved, but in some patients the lymph node architecture is disrupted by a polymorphic lymphocytic infiltrate. Lymphoid aggregates with an abnormal architecture may also develop in the skin, bone marrow, or other tissues. This atypical lymphoid hyperplasia may be difficult to differentiate from a malignant lymphoma.

ORIGIN AND PATHOGENESIS

Although some CVID patients have minimal numbers of circulating B cells, the majority have normal quantities of IgA, IgG, and IgM-bearing B-cell precursors in the blood. Defects in B-cell survival, number of circulating CD27⁺ memory B cells (including IgM⁺CD27⁺ B cells), B-cell activation after antigen receptor cross-linking, T-cell signaling, and cytokine expression have been observed. A decrease in the relative numbers of CD4 to CD8 T cells is common. Cutaneous anergy is a frequent finding. Alteration of the CD4/CD8 ratio can reflect expansion of the

CD8 natural killer cell population or an increase in the subset of CD8⁺, CD57⁺ T cells and natural killer cells. In some patients inversion of the ratio reflects a true decline in the absolute number of CD4 helper T cells.

The TNF family members B-cell activating factor of the TNF family (BAFF) and a proliferation-inducing ligand (APRIL) can induce isotype switching in naïve human B cells.²³ APRIL and BAFF bind to two receptors, B-cell maturation antigen (BCMA) and TACI, both of which are members of the TNF-R family. BCMA is exclusively expressed on B cells, whereas TACI is expressed on B cells and activated T cells. A third receptor, BAFF-R, which is unique for BAFF, is mainly expressed on B cells but also on resting T cells. In two seminal studies,^{22, 26} TACI mutations were found in 18 (10%) of 182 CVID patients, and in one of 16 IgAD patients. As is typical for CVID, symptoms in family members with TACI mutations ranged from severe to mild to nonexistent.

Function-loss mutations in the genes for ICOS, an immune co-stimulator molecule used by T cells to activate B cells in germinal centers, BAFFR, and CD19, the B-cell co-stimulatory receptor, have also been reported in isolated CVID patients. All of these genes play key roles in the maturation, proliferation, and longevity of mature B cells.

A large array of genes that play important roles in the control of the immune response are located in the MHC on chromosome 6 (Chapter 5). Studies at the University of Alabama at Birmingham have shown that in the southeastern USA the majority of IgAD and CVID patients share parts or all of one of two extended MHC haplotypes marked by either HLA-DR3,-B8 or HLA-DR7,-B44. The combined results of three studies of patients from Alabama, New England, and Australia indicate a 13% prevalence of immunodeficiency in individuals homozygous for HLA-DR3,-B8. Remarkably, several individuals with TACI mutations had also inherited MHC haplotypes associated with the disease,²² suggesting the possibility of epistatic interactions between the MHC and TACI alleles. A deficiency of IgG subclasses and IgA may also develop in complement C2-deficient patients.²⁷ The typical presenting manifestation of CVID is hypogammaglobulinemia, not agammaglobulinemia, suggesting a partial or varying block in B-cell maturation. Careful analysis of B cells in patients has also revealed a spectrum of immune deficiency ranging from the nearly complete absence of memory B cells to a less severe disorder. All of these findings serve to underline the complex etiology for the disorder, and many details remain to be elucidated.

TREATMENT AND PROGNOSIS

Therapy in CVID begins with the aggressive treatment of ongoing infections and the institution of prophylactic measures to prevent or ameliorate future infection. Patients suffering from moderate upper respiratory tract infections and bronchitis will likely benefit from empiric therapy with agents effective against encapsulated organisms such as *Haemophilus influenzae* and *Streptococcus pneumoniae*. Patients with recurrent pneumonia and evidence of bronchiectasis may be infected with *Pseudomonas*, *Staphylococcus aureus*, or other aggressive organisms, thus every effort should be made to identify the inciting agent. The course of treatment for immunodeficient patients is often prolonged and intravenous administration of antibiotics may be required.

The most effective therapy for hypogammaglobulinemic patients is replacement therapy with human immunoglobulin. A number of studies have demonstrated a steadily decreasing incidence of infection with increasing frequency of immunoglobulin administration. At higher doses, even patients with bronchiectasis may experience improvement

in pulmonary function. Each patient may demonstrate his or her own individual response to therapy, exhibiting dramatic differences in the frequency and severity of infections with moderate changes in the replacement dose. Patients suffering from a serious acute infection often benefit from one-time booster doses of immunoglobulin. Ultimately, replacement dosage must be individualized based upon the response of the patient. Adverse reactions occur most frequently at the time of the first administration of immunoglobulin, likely because of concurrent infection increasing the potential for generation of immune complexes. If the patient demonstrates no evidence of adverse reactions, administration of intravenous or subcutaneous immunoglobulin can be performed at home.

Some patients with CVID can sustain severe anaphylaxis when given intravenous immunoglobulin or other blood products that contain serum or plasma. These patients may possess anti-IgA antibodies, including IgE anti-A antibodies.²⁸ For patients with a history of severe adverse reactions, it is advisable to try lots of intravenous immunoglobulin with the lowest IgA possible and to test the patient with the different lots in an intensive care unit. Once having identified a lot that can be tolerated, the patient may receive therapy under more relaxed conditions.

Serum immunoglobulin concentrations in patients with CVID may change over time,² with rare patients regaining normal serum IgG levels and no longer requiring immunoglobulin therapy. Careful review of the clinical history of these patients may reveal evidence of exposure to pharmacologic agents associated with the development of hypogammaglobulinemia (e.g., phenytoin). However, the overwhelming majority of patients require replacement therapy for life.

Although IgG may be replaced, at present IgM and IgA cannot be provided to the patient. The absence of these multimeric proteins may help explain why even patients on high-dose replacement therapy may continue to suffer from chronic sinusitis or diarrhea. In such cases, patients often benefit from continued prophylactic therapy with antibiotics effective against encapsulated bacteria. Patients with CVID are also at risk from *Giardia lamblia*, as well as other enteric pathogens. Patients with chronic diarrhea often respond to treatment with empiric antibiotic therapy. Some patients develop gluten-sensitive enteropathy or lactose intolerance. These conditions often improve with avoidance of the inciting agent.²⁹ Others develop a malabsorption syndrome that can lead to hypoalbuminemia and hypocalcemia (due to malabsorption of vitamin D), and decreased levels of vitamin A and carotene.³⁰ The cause of diarrhea and malabsorption in this latter patient subset remains unclear, and treatment is limited to supportive measures, with vitamin and mineral replacement as indicated.

Patients with bronchiectasis should be treated aggressively with replacement therapy. In severe cases, aggressive pulmonary toilet will benefit the patient, including bronchodilator therapy, position and postural drainage, or other physical therapies. The use of corticosteroids should be avoided.

Splenomegaly is common in untreated patients. Hypersplenism in most patients responds to aggressive therapy with antibiotics and intravenous immunoglobulin. The presumption is that the hypersplenism is secondary to reactive hyperplasia of lymphoid follicles within the spleen attempting to respond to infection. Development of esophageal varices or other hematologic manifestations of hypersplenism (refractory thrombocytopenia, anemia, neutropenia, and lymphopenia) may require splenectomy as a therapy of last resort. The outcome for most such patients has been good, with resolution of symptoms. However, the risk of infection from encapsulated organisms increases in such patients, and they should be placed on penicillin prophylaxis (or an equivalent).

IgA-deficient mothers fail to secrete IgA in their colostrum.³¹ Although colostral IgM levels may be elevated in an attempt to compensate for the lack of maternal IgA, the newborn remains relatively unprotected against intestinal pathogens. Of greater concern are the children of mothers with untreated CVID who are born in a state of humoral immunodeficiency and are at great risk for life-threatening sinopulmonary infection. In order to compensate for the loss of IgG across the placenta and to provide the infant with the passive immunity it will require, the level of intravenous immunoglobulin infusion should be increased to 600 mg/kg during the third trimester of pregnancy.

■ SELECTIVE IGG SUBCLASS DEFICIENCIES ■

DIAGNOSIS

A diagnosis of clinical immunodeficiency should be supported by clear evidence of functional impairment. Most individuals with modest reductions in serum IgG subclass levels are functionally normal. Indeed, individuals with deletions of the heavy-chain immunoglobulin gene locus, some of whom completely lack IgG₁, IgG₂, IgG₃, and IgA₁,³² have been reported to be asymptomatic. This experiment of nature is a further reminder of the fact that absence of serum immunoglobulin is not necessarily synonymous with clinical immune deficiency.

The diagnosis of a functional IgG subclass deficiency can thus be made with confidence only when the concentration of a specific isotype is significantly depressed and there is clear evidence of abnormal specific antibody production. Among patients with deficiency of IgG₁ or IgG₃, protective titers of antibodies in response to standard tetanus toxoid and diphtheria immunizations indicate the production of adequate anti-protein antibodies and make associated immunodeficiency unlikely. Among patients with clinically significant IgG₂ deficiency, specific antibody production in response to a carbohydrate vaccine is decreased. IgG₂ levels normally begin to rise in childhood later than other subclasses, and a low value in a child may be a temporary finding. Up to 10% of normal males and 1% of normal females are IgG₄-deficient, which makes a diagnosis of immunodeficiency as a result of an isolated IgG₄ subclass deficiency problematic.

CLINICAL MANIFESTATIONS

The clinical spectrum of isolated IgG subclass deficiency is quite variable and deficiencies of each of the four IgG subclasses have been described. Some individuals are referred to the clinical immunologist with only a mild reduction of total IgG, but most symptomatic patients have marked deficiencies of one or more IgG subclass despite normal total IgG concentrations. Typically patients with IgG₁ deficiency exhibit depressed total serum immunoglobulin levels, as well.

Determination of IgG subclasses is rarely performed on asymptomatic individuals, thus most patients with an isolated IgG₂ deficiency come to medical attention as a result of recurrent sinusitis, otitis media, or pulmonary infections. Individuals may have few residual symptoms between infections, but some have severe chronic inflammation with refractory sinusitis, pulmonary fibrosis, or bronchiectasis. Because protective antibodies directed against carbohydrate antigens are usually of the IgG₂ subclass, many affected patients exhibit an impairment of their ability to

mount specific protective responses to encapsulated pathogens. However, normal responses have also been described.³³ The response to polysaccharides is typically tested by challenge with a pneumococcal polysaccharide vaccine. Diagnosis is complicated by the fact that interpretation of pneumococcal polysaccharide vaccine responses remains controversial. Many clinicians would agree, however, that IgG₂-deficient patients who suffer with recurrent sinopulmonary infections and who respond to less than half of the polysaccharide antigens with which they have been challenged meet the standard for functional immune deficiency. Such patients warrant aggressive prophylactic therapy up to and including immunoglobulin replacement should the infections be severe.

IgG₃ deficiency may occur alone or in association with IgG₁ deficiency. Recurrent infection of the respiratory tract with chronic lung disease has been reported. With a serum half-life of only 2 weeks, IgG₃ levels may be consumed rapidly during the course of an active infection in an otherwise normal individual.³⁴ Before making the diagnosis of IgG₃ deficiency, serum levels of IgG₃ should be rechecked when the individual is asymptomatic.

When compared with the serum, IgG₄ is over-represented in secretions, and IgG₄-committed B cells are present at mucosal sites, suggesting a role in mucosal immunity. Since IgG₄ is normally present in the serum in very low concentrations, the significance of a low serum level in a patient with recurrent infection remains unclear.

ORIGIN AND PATHOGENESIS

The origin of IgG subclass deficiency is unknown. Homozygous deletions of portions of the immunoglobulin heavy-chain constant locus associated with total absence of IgG₂, IgG₃, and IgG₄ or combinations of these isotypes have been described in healthy individuals. IgG₂ deficiency is often found in association with selective IgA deficiency with or without IgG₄ deficiency, and patients with selective IgG subclass deficiencies have been shown to have inherited the same MHC haplotypes as those who suffer with IgAD and CVID.¹⁸ These observations suggest that patients with recurrent infections have a more complex defect than the mere elimination of one or more IgG isotype. In some instances, subclass deficiency is associated with a T-cell defect, as in chronic mucocutaneous candidiasis and ataxia-telangiectasia. IgG subclass deficiency may also be acquired. Acute infections, medications, chemotherapy, irradiation, surgery, and HIV infection have all been temporally linked to the development of a deficiency in one or more IgG subclass.³⁵

TREATMENT AND PROGNOSIS

The natural history of IgG subclass deficiency, especially in children, is not constant. Some children improve, whereas for others subclass deficiency may progress into frank CVID. Associated allergic rhinosinusitis and asthma must be aggressively treated with conventional therapy for these disorders, as these conditions increase the risk of purulent sinusitis and pneumonia. Causes of anatomic obstruction should be sought when persistent infection of a sinus or pulmonary segment is the presenting complaint; the role of surgical therapy for anatomic obstruction should not be overlooked. Most patients with IgG subclass deficiency do well on prophylactic antibiotics and will never need immunoglobulin supplementation.

Immunoglobulin replacement therapy should only be considered in patients with severe, recurrent infections. Patients who begin therapy should improve within the first 2 months, but to avoid the placebo effect, a full 6-month trial is recommended. A reduction in frequency of viral

respiratory infections is likely to occur in any individual receiving intravenous immunoglobulin because of the broad spectrum of antibodies present, thus relative freedom from trivial infections should not be taken as evidence of need for permanent replacement therapy.

ANTIBODY DEFICIENCY WITH NORMAL SERUM IMMUNOGLOBULIN LEVELS

Occasional patients may present with normal serum immunoglobulin concentrations and a selective inability to respond to infections with pyogenic organisms. Diagnosis requires documentation of an inability to respond to antigenic challenge. These patients may respond to replacement immunoglobulin therapy. The antibody response to specific polysaccharide antigens can be very selective. In humans, most protective anti-*Haemophilus influenzae* type b (anti-Hib) antibodies utilize the rare V κ A2 gene.³⁶ The Navajo population in the southwestern USA suffers a 5–10-fold increased incidence of Hib disease. This population also exhibits a high prevalence of an A2 allele with a defective recombination signal sequence, preventing use of germline-encoded antibodies that can generate protective antigen-binding sites. It is likely that many more such subtle defects that underlie susceptibility to infectious diseases will be identified in the coming years.

A recent analysis of a group of well-characterized patients, mostly female, with a history of RESPI and normal serum immunoglobulin levels revealed a high prevalence of the same MHC haplotypes observed in IgAD, selective IgG subclass deficits, and CVID.²⁰ This is further evidence that the presence of serum immunoglobulin is not necessarily synonymous with clinical immune sufficiency. These patients tend to respond to aggressive antibiotic therapy, including prophylaxis.

SELECTIVE LIGHT-CHAIN DEFICIENCY

A selective deficiency of κ light chains has been reported in 3 patients, and a selective deficiency of λ light chains has been reported in a fourth.^{37,38} In one case, the patient was the offspring of a consanguineous (uncle–niece) union;³⁹ and in the second, a molecular analysis demonstrated different loss-of-function mutations in the patient's C κ alleles.⁴⁰ The parents of these children had no health difficulties, but each of the patients required medical attention for recurrent sinopulmonary infections and diarrhea. Two of the κ -deficient patients exhibited IgA deficiency and the remaining κ -deficient and the λ -deficient patients were panhypogammaglobulinemic.

TRANSIENT HYPOGAMMAGLOBULINEMIA OF INFANCY

DIAGNOSIS

As infants make the transition from dependence on maternal immunoglobulin to reliance on endogenously produced antibodies, they experience a physiologic nadir of serum immunoglobulin at 4–6 months of

age, a period associated with susceptibility to mild upper respiratory infections and otitis media (Fig. 34.2). Children, both male and female, who: (1) exhibit serum concentrations of one or more of the three major immunoglobulin classes that fall below the 95% confidence interval for age on two or more occasions during infancy; (2) demonstrate a rise in these values to or toward normal over time; and (3) lack features consistent with other forms of primary immunodeficiency, fall within the catch-all diagnosis of transient hypogammaglobulinemia of infancy (THI).⁴¹ By definition, the diagnosis of THI can be made with certainty only in retrospect. The great majority of infants with THI will have substantial levels of IgM and detectable IgA by 6–12 months of age. Since absence of IgA is the most common finding in permanent antibody deficiency syndromes, the presence of this isotype in an infant with low IgG and IgM supports the diagnosis of THI. THI likely represents a heterogeneous group of genotypes with a single common end-point.

CLINICAL MANIFESTATIONS

Immunoglobulin concentrations are rarely measured in infants unless there is some reason to suspect an immunodeficiency. Most patients with this diagnosis come to medical attention due to recurrent infections or as a consequence of routine screening studies of relatives of other immunodeficient patients. Yet bearing in mind that 2.5% of normal infants will fall below the 95% confidence range at any one time, the diagnosis of THI is remarkably rare. Among two major centers, one in the USA and one in Germany, the diagnosis was given to only 16 of 18 000 children in whom the index of suspicion warranted immunoglobulin determinations.^{41, 42}

Patients with THI are typically able to synthesize specific antibodies in response to immunization with T-dependent antigens (e.g., tetanus and diphtheria toxoids).⁴¹ They may have difficulty, however, responding to polysaccharide antigens (e.g., isohemagglutinins and Pneumovax). Some will fail to sustain protective antibody responses to antigen. Most patients with THI, especially those ascertained as a result of family studies or mild upper respiratory infections alone, exhibit fewer infections over time. Patients with a history of invasive infections or an inability to respond appropriately to immunization may continue to suffer from infection and thus warrant therapy.⁴³

TREATMENT AND PROGNOSIS

Children should be monitored with serial determination of serum immunoglobulins and isohemagglutinin titers in order to confirm acquisition of normal immune function. Some children will not achieve normal levels of IgG for several years, and some will remain IgG subclass or IgA-deficient. Treatment of transient hypogammaglobulinemia with intravenous immunoglobulin is generally not warranted unless the child suffers from persistent, recurrent, invasive infections, including pneumonia.

Primary T-cell immunodeficiencies

Françoise Le Deist, Alain Fischer

35

INTRODUCTION

Primary deficiencies of the acquired immune system are studied according to the type of lymphocyte most affected, and broadly categorized into T- and B-cell immunodeficiencies. This chapter describes primary T-cell immunodeficiencies; Chapter 34 is devoted to primary B-cell immunodeficiencies. Hematopoietic stem cell transplantation (HSCT) and gene therapy, the only available curative treatments for primary immunodeficiencies, are reviewed in detail in Chapters 83 and 86.

Primary T-cell immunodeficiency diseases originate from inherited defects of the components of the immune system involved in T-cell differentiation and function, i.e., T cells, their precursors, the thymic environment, and antigen-presenting cells. Because of the central place of T cells in immune responses, T-cell deficiencies not only affect T-cell effectors of the immune response, such as cytotoxic T cells, but also other effector cells that are activated by T cells, such as monocytes/macrophages and B cells. Profound T-cell deficiencies thus usually present as 'combined' immunodeficiencies of the different arms of the immune response. They generally present with clinical manifestations within the first year of life, although moderate deficiencies can manifest much later (up to adulthood). Statistical data from national primary immunodeficiency registries suggest that primary T-cell immunodeficiencies represent 20% of all symptomatic primary immunodeficiencies.

T-cell immunodeficiencies increase susceptibility to infections, particularly those caused by intracellular microorganisms, which may persist inside cell niches protected from immune mechanisms. Recurrent infections, chronic diarrhea and malabsorption are frequently associated with failure to thrive. Allergy, autoimmunity and lymphomas are other important characteristics of T-cell immunodeficiency, occurring with a higher frequency than in healthy individuals.

Primary T-cell immunodeficiencies can be classified into four groups according to their severity and associated features: severe combined immune deficiencies (SCIDs); T-cell immunodeficiencies with detectable T cells; T-cell immunodeficiencies with associated nonimmune defects; and miscellaneous immunodeficiencies in which the T-cell defect is less apparent than the resulting immune dysfunction.

SEVERE COMBINED IMMUNODEFICIENCIES (SCIDs)

This group of genetic disorders is characterized by profoundly defective T-cell differentiation, with or without abnormal B- and NK-cell differentiation, that leads to early death in the absence of hematopoietic stem cell transplantation (Table 35.1).¹ The overall frequency of SCID has been estimated at 1:50 000–1:100 000 live births. Various forms of SCID have been defined, based on enzymatic, genetic and immunologic criteria (Table 35.1).

CLINICAL PRESENTATION

Patients with SCID are characterized by early onset of infections, mainly of the respiratory tract and gut. The frequency of infections and the diagnosis in 117 patients with SCID who were referred to our center are shown in Table 35.2.² Oral candidiasis, persistent diarrhea with growth impairment, and/or interstitial pneumonitis were the most frequent infectious manifestations leading to diagnosis. There were no clinical differences between the various SCIDs, except for an earlier onset of infections in patients with adenosine deaminase (ADA) deficiency. The persistence and recurrence of infections led rapidly to growth impairment and malnutrition. Similar findings have been reported independently in another cohort of SCID patients.³

Common opportunistic organisms such as *Pneumocystis jiroveci* and *Aspergillus* species frequently cause infection in SCID patients. Intracellular organisms such as *Listeria* and *Legionella* can cause devastating disease, as can viruses, especially those of the herpes group and adenoviruses. Epstein–Barr virus (EBV) infection, although rare in this age group, can lead to uncontrolled B-lymphocyte proliferative disorders (BLPD) in B(+) SCID patients, as seen in immunosuppressed transplant recipients. Live vaccines can also cause life-threatening infections. We have observed BCG disease in 10 of 28 vaccinated patients, including two with local infection and eight with involvement of the liver, spleen and lungs, which was fatal in three cases.² Based on this experience and similar reports from other

Table 35.1 Classification of SCID

Disease	Relative frequency	Inheritance	Cells affected	Gene product	Other

specialized centers, children with SCID or suspected to have SCID should not receive live vaccines.

Noninfectious clinical manifestations in SCID patient consist mainly of graft-versus-host disease (GVHD) caused by the patients' inability to reject allogeneic cells. The two possible sources of allogeneic cells are maternal lymphocytes and blood product transfusions. Circulating maternal T cells are detected in approximately 50% of cases. Maternal T-cell numbers range from 10 to several thousand/mm³ of blood, and usually have a normal phenotype with poor lymphoproliferative response to mitogens, and circulate with some degree of *in vivo* activation, as shown by the expression of MHC class II molecules and/or the IL-2 receptor. The most intriguing observation regarding maternal T-cell engraftment in SCID patients is the paucity of clinical manifestations. In the majority of cases the presence of maternal T cells is entirely asymptomatic, but approximately 30–40% of patients have mild symptoms and signs, such as erythema and scaly skin with skin T-cell infiltration, eosinophilia, and elevated liver enzymes with periportal T-cell infiltration.² The presence of maternal T cells should not delay the diagnosis of SCID because of detection of some T cells in the periphery. It may be an obstacle to T-cell engraftment following T cell-depleted haploidentical bone marrow transplantation (BMT), especially if the donor is not the mother and if the patient is not treated with myeloablative and immunosuppressive drugs. In case of HLA-identical BMT, there is usually a dramatic expansion of donor T cells cytotoxic for maternal cells 10–12 days post BMT, which results in their rapid elimination. This 'graft-versus-graft' reaction may cause transient GVHD symptoms. In contrast, postnatal inoculation with allogeneic lymphocytes by transfusion of plasma, red cells, platelets or white cells usually causes a fatal acute GVHD syndrome, marked by diffuse necrotizing erythroderma, gut mucosa abrasion and destruction of the biliary epithelium, and is sometimes associated with stromal cell lesions in the marrow. This GVHD syndrome can occur within 2–4 weeks and is usually resistant to the most powerful immunosuppressive drugs. GVHD does not develop in a small number of cases, although allogeneic anti-host T cells can be detected and cause resistance to BM engraftment.⁴ Prevention of this complication relies on T-cell depletion and irradiation of all blood products given to patients in whom SCID is suspected or cannot be excluded.

SCID patients present with profound hypoplasia of secondary lymphoid organs. The thymus is also hypotrophic, with an absence of the lymphoid component and defective differentiation of epithelial cells. There are no Hassall's corpuscles. This absence does not reflect a primary abnormality of the epithelial component of the thymus, as it becomes functional after BMT. It also indicates that the influx of hematopoietic lymphoid precursors is necessary for the differentiation of the thymic epithelium.

DIAGNOSIS

The diagnosis of SCID is suggested when there is a family history (especially in the mother's pedigree) of early death from infections and the symptoms described above. However, most SCID cases are sporadic and are diagnosed after immunologic studies are performed in an infant with unusually severe or frequent infections. In most cases, clinical examination together with very simple tests can confirm a suspicion, i.e., lack of palpable lymph nodes, especially in the inguinal area, with absence of visible tonsils, absence of a thymic shadow on the chest X-ray, and lymphocytopenia. The latter is of great value in young children, as normal absolute lymphocyte counts are high (around 6000/μL; Fig. 35.1). For example, only six out of 59 SCID patients studied in one case series had normal (or increased) lymphocyte counts.⁵ Enumeration of blood T, NK and B cells, mitogen-induced lymphocyte proliferation assays, and determinations of adenosine deaminase activity are important diagnostic tests to diagnose the form of SCID. Costochondral dysplasia and, in some cases, unusual neurological manifestations (blindness, dystonia) are additional specific signs of ADA deficiency. Detection of gene mutations is important to confirm the clinical diagnosis, and for the appropriate choice of BMT treatment protocol and genetic counseling.

The differential diagnosis of SCID includes other diseases with reduced T-cell numbers, including HIV infection with severe immunodeficiency, rare cases of late-onset rubella with transient T-cell lymphocytopenia, and DiGeorge syndrome.

Given the importance of an early diagnosis in order to reach a better prognosis for BMT,⁶ neonatal screening for severe T-cell immunodeficiency has been sought. One approach proposes the use of a Guthrie card

KEY CONCEPTS

THERAPEUTIC PRINCIPLES: SEVERE COMBINED IMMUNE DEFICIENCIES (SCID)

- >> Children at risk for SCID must not be given live viral vaccines.
- >> All blood products administered to patients at risk for SCID must be irradiated before transfusion.

to detect the presence (or the absence) of T-cell receptor excision circles (TREC) in neonate blood samples, as a demonstration of functional thymopoiesis, using PCR technology.⁷

MANAGEMENT

Primary immunodeficiency patients require specialized care for diagnosis, treatment and follow-up. When a patient is suspected to have SCID, prompt immunologic evaluation is urgent in order to provide treatment before new severe and debilitating infections occur. In addition, the patient should not receive live vaccines, and if required, blood product transfusion should be irradiated, T cell-depleted, and tested negative for CMV antigen. Antibiotic prophylaxis is also indicated. Isolation measures are relative to the risk of infection with human pathogens, taking into consideration the patient's psychosocial needs.

Curative treatment for SCID is hematopoietic stem cell transplantation, which has been performed under protocols that differ regarding the

KEY CONCEPTS

SEVERE COMBINED IMMUNODEFICIENCY

- >> Common element among various types of SCID is extremely low number of mature T cells.
- >> B cells, present in several types of SCID, are nonfunctional, presumably because of lack of T-cell interaction.
- >> Frequent opportunistic infections and unusual infections with routine pathogens lead to early demise by 1–2 years of life unless T-cell pool is reconstituted by BMT.
- >> Molecular lesions in chromosomes, genes, and gene products now being discovered may lead to more selective approaches to therapy.

donor source, the processing of the graft and the myeloablative conditioning employed. Success rates for each form of SCID treatment may not be similar (Chapter 83), emphasizing the importance of molecular diagnosis.

SCID DISEASES

Over 96% of SCID cases can be explained by four mechanisms of disease: defective VDJ recombination, defective cytokine receptor signaling, defective adenosine deaminase causing accumulation of toxic metabolites, and defective TCR signaling.

KEY CONCEPTS

CLINICAL PEARLS: FEATURES OF T-CELL DEFECTS

- >> Functional deficiencies yield to discovery of molecular defects, e.g. hyper-IgM syndrome is now known as a T-cell defect (CD40 ligand deficiency on T cell).
- >> Many T-cell deficiencies are due to defects in signal transduction proteins.
- >> Severity of SCID is due to common γ -chain defects in IL-2R, IL-4R, IL-7R, IL-9R, IL-15R and IL-21R.
- >> Defects in nonlymphocyte specific genes affect T-cell development, e.g. ADA deficiency, AT.

Defective VDJ recombination

Autosomal recessive SCID – alymphocytosis (T-, B-, NK+ SCID)

About 20% of patients with SCID have a phenotype characterized by the absence of T and B cells; however, functional natural killer (NK) cells can be detected. These findings are similar to those found in murine SCID, which is manifested by defective V(D)J recombination of T-cell receptor (TCR) and immunoglobulin (Ig) genes (Fig. 35.2) (Chapter 4). Signal joints are formed normally but the coding segments fail to join. The murine SCID defect is caused by mutations of the gene encoding the DNA-dependent protein kinase (DNA-PK).⁸ In the absence of this enzymatic activity, coding joints cannot be formed and the hairpin extremities of the V(D)J coding sequences are left apart. DNA-PK is involved in a DNA repair mechanism, i.e., nonhomologous end joining (NHEJ), utilized in the V(D)J recombination process, as all cell types of SCID mice exhibit a double-strand DNA break repair.⁹ Despite phenotypic similarity, including defective V(D)J recombination as shown in marrow B-cell precursors, no SCID patients lacking T and B cells exhibit DNA-PK mutations.

Two forms of T- B- SCID can be recognized according to cell radiosensitivity. In approximately half of the patients marrow progenitor cells or fibroblasts exhibit increased cell radiosensitivity. In the other half, there is no detectable radiosensitivity anomaly. The latter phenotype results from mutations in the *RAG-1* or *RAG-2* genes.¹⁰ RAG-1 and RAG-2 proteins are located in the nucleus of lymphoid progenitor cells undergoing the V(D)J recombination process¹⁰ (Fig. 35.2). These proteins initiate the recombination process by interacting with the DNA recognition signal sequences that flank the coding regions, inducing a precisely targeted double-strand DNA break between the coding sequence of a V, D or J element and the signal sequence. These DNA breaks form hairpins by a transesterification reaction. These hairpins are then further resolved and joined in a second step of the V(D)J recombination process (see above). A number of *RAG-1* and *RAG-2* gene mutations have been characterized to result in preventing DNA/RAG-1/2 complex interaction and DNA cleavage. As discussed below, mutations of these same genes allowing partial activity cause Omenn's syndrome, a condition characterized by oligoclonal T-cell expansion and immunodeficiency with $\gamma\delta$ T-cell expansion.¹¹

Fig. 35.1 Absolute lymphocyte counts in 59 infants with SCID at time of diagnosis. Top and bottom lines ± 2 SD limits, middle line mean of normal value. (From Gossage DL, Buckley RH. Prevalence of lymphocytopenia in severe combined immunodeficiency. *N Engl J Med* 1990; 323: 1422, with permission From the Massachusetts Medical Society.)

In those cases in which the block of T-/B-cell development and V(D)J recombination deficiency is associated with increased cell radiosensitivity, the SCID phenotype is caused by mutations of the *Artemis* gene.¹² This phenotype is observed with a high frequency (1:2000 live births) in North American Indians speaking the Athabascan language. Research in this ethnic group assigned the disease gene locus to the short arm of chromosome 10, which was subsequently confirmed in other ethnic backgrounds.¹³ The *Artemis* protein has a hydrolytic endonuclease activity that is able to cleave the hairpins formed by coding ends upon *RAG-1/-2* action. Although *Artemis* deficiency impairs the nonhomologous end-joining (NHEJ) DNA repair pathway, no other clinical consequences of the SCID phenotype have been found associated with *Artemis* deficiency. Hypomorphic mutations of *Artemis* have since been described associated either with Omenn's syndrome¹⁴ or a severe but partial T- and B-cell immunodeficiency with a risk of EBV-associated B lymphomas.

Defective cytokine receptor signaling

X-linked SCID (SCIDX1) (T-, B+, NK- SCID)

SCIDX1 is characterized by defective T- and NK-cell differentiation, although B-cell maturation is preserved. Patients usually lack mature T cells but have a normal or increased number of B cells. Like autosomal recessive SCID, SCIDX1 can be treated by hematopoietic stem cell

Fig. 35.2 Scheme of V(D)J gene rearrangement. The rearrangement process is divided into three steps: 1) RAG1 and RAG2 bind the RSS (recombination specific sequence), and perform single-DNA strand breaks (nick). They then form the synaptic complex in association with the architectural protein HMG1. The DNA double-strand break is performed within this complex, and the coding ends are in the form of hairpins. 2) The complex Ku70/80-DNA-PK recognizes the DNA breaks. The hairpins are opened by Artemis. 3) The recruitment of the protein XRCC4 and Cernunnos lead to the ligation action of ligases such as ligase IV. During this step, the terminal deoxynucleotidyl transferase (TdT) adds random nucleotides (N), thus increasing the diversity of the Variable chain.

transplantation (HSCT). This is the most frequent form of SCID, accounting for about 50% of cases.²

Precursor thymocytes are not detected in the thymus of patients with SCIDX1, indicating an early block in T-cell differentiation. Studies of X-chromosome inactivation patterns in obligate carriers have shown a skewed pattern not only in T cells but also in B cells and NK cells, whereas in the other hematopoietic cell lineages there is usually a random pattern.¹⁵ The involvement of the product of the mutant SCIDX1 gene in B-cell maturation is also suggested by the observation that patients' B cells exhibit moderate phenotypic and functional anomalies. Following HSCT¹⁶ the B-cell immunodeficiency is usually not functionally restored, thus requiring immunoglobulin substitution.^{17, 18} This gene defect also results in faulty NK-cell differentiation.

Studies examining restriction fragment length polymorphisms (RFLP) in families localized the gene encoding SCIDX1 to Xq12-13.1, and subsequent gene mapping efforts determined that mutations in the gene encoding the IL-2 receptor γ chain were responsible for the SCIDX1 phenotype. Following binding of IL-2, the association of the IL-2 receptor γ chain (71 kDa) with the IL-2 receptor β chain is necessary for expression and signal transduction. The high-affinity IL-2 receptor comprises IL-2 receptor α , β and γ chains. Like the β chain, the γ chain is constitutively expressed by T cells. The IL-2 receptor γ chain gene (*IL2RG*) has been cloned and shown to map to Xq12-13, as does the SCIDX1 locus. These results were somewhat surprising, as in IL-2-defective mice T-cell differentiation occurs (although an immunodeficiency ensues) and IL-2 deficiency in humans (see below) is also associated with T-cell differentiation. This difference suggested

that the IL-2 receptor γ chain may be part of another critical receptor for T-cell differentiation, leading to the subsequent demonstration that IL-2 receptor γ chain was also a member of one form of the IL-4 receptor, as well as the IL-7R, the IL-9R, the IL-15R, and the IL-21R (Fig. 35.3)¹⁹ (Chapter 10). The IL-2 receptor γ chain has thus been named γ_c (c for common). Comparison of phenotypes of γ_c^- mice and IL-7 or IL-7R α^- mice has shown that this faulty interaction of IL-7 with its receptor results in the block in T-cell development.²⁰ The IL-7 receptor is expressed very early in hematopoietic cell development. IL-7–IL-7R interaction delivers three different signals to thymocytes, i.e., for survival, for proliferation, and for differentiation.²¹ Defective IL-15–IL-15R interaction similarly causes the block in NK-cell development, explaining the absence of NK cells in SCIDX1 patients.²² IL-4 and IL-21 receptor deficiencies account for dysfunctional B cells. Multiple mutations of the γ_c gene have now been reported.²³ Most affect the extracellular region of the molecule.

Fig. 35.3 γ_c -Dependent cytokines in early lymphoid development. The hematopoietic and lymphoid lines derived from a pluripotent stem cell. The NK and T-lymphocyte lineages differentiate under IL-15 and IL-7 effects, respectively. The γ_c chain is shared by IL-2R, IL-4R, IL-7R, IL-9R, IL-15R and IL-21R. Conserved cysteines are shown as orange; WS (tryptophan-serine) motif shown as yellow. (From Di Santo J, Muller W, Guy-Grand D, et al. Lymphoid development in mice with a targeted deletion of the interleukin 2 γ chain. *Proc Natl Acad Sci USA* 1995; 92: 377, with permission From the National Academy of Sciences, USA.)

Atypical X-linked SCID

A combined X-linked immunodeficiency characterized by progressive loss of T- and B-cell function leading to death during childhood has been described in several families. In two families, T cells were found to be oligoclonal,²⁴ and in one family the X-chromosome inactivation pattern in obligate carriers, together with gene mapping by RFLP studies, suggested a form of SCIDX1. Analysis of the γ_c gene in one of these cases demonstrated two transcripts, one truncated and one of normal size, which accounted respectively for 80% and 20% of total γ_c mRNA.²⁵ A single base-pair substitution in the last position of exon 1 was found to probably disturb splicing of intron 1 (resulting in the abnormal mRNA product), whereas a less frequent normal splicing generated the normal-sized mRNA. This transcription abnormality resulted in a reduced number of normal, high-affinity IL-2-binding sites. In another case, presenting with normal numbers of T and B cells, T cells were shown to proliferate in the presence of mitogens, but IL-2 binding to T cells was reduced.²⁶ A mutation of γ_c (R222C) caused the reduced binding to IL-2. This case might thus be the consequence of defective IL-2–IL-2R interaction, although interaction of the γ_c receptor with other cytokines important in T-cell development, such as IL-7, is preserved. This is in contrast with the converse observation of a SCIDX1 phenotype caused by a γ_c mutation (A156V) affecting IL-7 (and IL-4)-mediated responses, but less so IL-2 and IL-15-mediated responses.²⁷

Other atypical X-linked SCID cases included two examples of phenotype reversion. In one patient, despite a γ_c gene deletion encompassing most of the intracellular domain of γ_c , the child developed partially functional T cells that were of host origin following an unsuccessful attempt at BMT. Such T cells were detected over an 8-year period following BMT, albeit in declining numbers. Another atypical SCIDX1 patient developed an unusual phenotype characterized by the presence of host T cells (800–2000 T cells/mm³) that were able to respond (albeit not normally) to mitogens and antigens.²⁸ Although γ_c expression could not be detected on the patient's B cells, monocytes and granulocytes, T cells did express γ_c . The γ_c gene was found to be mutated in B cells (Cys→Arg substitution at position 115) but not in T cells. These results could be explained by a reverse mutation that occurs in a T-cell progenitor, differentiating into a somewhat diverse pool. By immunoscope combined with sequencing analysis, it was determined that the T-cell repertoire of this child accounted for at least 1% of the repertoire of memory T cells of a normal individual. This indicates that T-cell precursors can divide at least 10–11 times prior to the stage of *TCRB* gene rearrangement. The selective advantage conferred to this cell lineage appears very high, giving support for the feasibility of gene transfer as a treatment of SCIDX1,²⁹ even if conditions of hematopoietic stem cell transduction are very inefficient with currently available vectors.

SCID: JAK 3 deficiency (T⁻, B⁺, NK⁻ SCID)

A SCID phenotype similar to that of SCIDX1 is observed with an autosomal recessive pattern of inheritance in approximately 10% of cases.³⁰ This observation led to the hypothesis that a molecular block downstream of the γ_c gene could cause this condition. The immediate downstream molecule, JAK3 (Janus-associated kinase) is associated with the intracellular part of γ_c , is phosphorylated upon ligand binding to the receptor, and phosphorylates the Stat5 molecules.³⁰ Patients were indeed found to exhibit mutations in the *JAK 3* gene. The majority of described mutations affect protein expression or stability, or less commonly, result

in a nonfunctional JAK3 protein. Missense mutations and small in-frame deletions may permit protein expression but interfere with kinase activity and/or γc binding. Some of these hypomorphic mutations were found in late-diagnosed patients with an atypical form of SCID characterized by oligoclonality of their T cells.³¹

SCID: IL-7R- α deficiency (T^- , B^+ , NK^+ SCID)

Some SCID patients present with a phenotype characterized by a selective absence of mature T lymphocytes, although maturation of NK and B cells is not affected. In most of these cases the molecular defect has now been elucidated to be mutations in the gene encoding the α chain of the IL-7 receptor.³² All the mutations reported are clustered in the first five exons of the gene encoding the extracellular part of the protein, regardless of the type of mutation (splice-site alterations, nonsense, missense, nucleotide deletion).³³ The severe phenotype associated with these mutations indicates that integrity of IL-7 receptor-mediated signal transduction is required to promote T-cell development.

Defective adenosine deaminase causing accumulation of toxic metabolites

Adenosine deaminase deficiency (T^- B^- , NK^- SCID)

About 20% of SCIDs are caused by adenosine deaminase deficiency. Adenosine deaminase (ADA) is a ubiquitous enzyme that reversibly transforms adenosine to inosine and 2'-deoxyadenosine (dAdo) to 2'-deoxyinosine (Fig. 35.4). The mechanism by which ADA deficiency leads to severe T, NK and B lymphocytopenia without

seriously affecting other tissues is explained by the accumulation of adenosine and dAdo substrates that are preferentially toxic to lymphocytes, and especially to immature lymphocytes (thymocytes). dAdo, which diffuses freely, is phosphorylated into deoxyATP. Unlike other cell lineages, immature lymphocytes and, to a lesser extent, mature lymphocytes are poorly able to reversibly degrade dATP into dAdo.³⁴

The ADA gene localizes to chromosome 20q13.11 and consists of 1089 nucleotides divided into 12 exons. Different deletions, missense mutations and splice mutations of the ADA gene that induce ADA-deficiency SCID have been characterized. Some missense mutations have been associated with partial ADA deficiency. Somatic reversions of gene mutations have been described in patients with ADA deficiency leading to the development of functional T cells.³⁵

In most cases (estimated at about 85%), ADA deficiency results in a typical SCID with very low T- and B-cell counts.² In addition to severe infections and failure to thrive, approximately 50% of patients with ADA deficiency can develop skeletal abnormalities consisting of cupping and flaring of the costochondral junction and mild pelvic dysplasia. Some patients have neurological problems, including cortical blindness, hearing disorders and dystonia. It is difficult to exclude a diagnosis of viral encephalitis, but resolution of neurological abnormalities following specific treatment of ADA deficiency suggests that they are a direct metabolic consequence of the enzyme deficiency. Mesangial sclerosis and abnormal renal function have been noted in some patients, as well as cortical adrenal fibrosis. It is not proven that the latter lesions are specific to ADA deficiency.³⁴

The typical, early-onset type of ADA deficiency is associated with barely detectable enzymatic activity in red cells and lymphocytes when erythrocyte dATP levels exceed 1000 ng/mL packed red cells. ADA

Fig. 35.4 Purine metabolism in lymphocytes. Pathway inhibition block in ADA or PNP deficiency.

gene mutations often affect the active site of the molecule or represent a deletion within the ADA gene. In some other patients, clinical onset is delayed by several months. T-cell lymphocytopenia may not be complete and there is often eosinophilia. In these patients, residual ADA activity may be found in lymphocytes. Late-onset ADA deficiency has also been described, with the first clinical manifestations occurring after 2, 3 or even 4 years. In these patients with a mild T-cell immunodeficiency, lymphocytopenia develops gradually. Autoimmune manifestations are not uncommon, as in other incomplete T-cell immunodeficiencies. For instance, refractory thrombocytopenic purpura at the age of 17 years has been described as the first manifestation of ADA deficiency.³⁴ In patients with late-onset ADA deficiency, dATP erythrocyte levels are usually less elevated than in the early-onset type (<1000 ng/mL packed red cells).

ADA deficiency is the only form of SCID that has a specific treatment to improve immune function, other than HSCT. Polyethyleneglycol-adenosine deaminase (PEG-ADA) is a bovine-derived enzyme that replaces the deficient enzyme to eliminate toxic metabolites, which leads to increased lymphocyte survival. PEG-ADA is administered subcutaneously at least once a week and may result in normalization of cellular and humoral immunity within 8–12 weeks.³⁴

Defective TCR signaling

CD3 δ , ϵ deficiency and CD45 deficiency

Lack of T-cell development may result from abnormal intracellular signaling after TCR binding. The CD3 complex, associated with the TCR, is composed of an assembly of four transmembrane proteins named CD3 δ , ϵ , ζ and γ . Mutations in the genes encoding CD3 δ and ϵ have been shown to cause SCID in eight patients from four unrelated families and in two patients from one consanguineous family.³⁶ Mutations in CD3 ζ and γ , and hypomorphic mutations in CD3 ϵ , cause milder forms of immunodeficiency. These mutations, including nonsense mutations and splice site alteration, interfere with membrane receptor protein expression. The phenotypic consequences of these CD3 deficiencies are a decrease in mature CD3 T cells in the periphery, including both TCR $\alpha\beta$ and TCR $\gamma\delta$ T cells.³⁶

Deficiency in CD45 signaling due to mutations in the CD45 gene have been described to be the cause of SCID in two patients.^{37,38}

Other SCIDs

Reticular dysgenesis

Reticular dysgenesis is a very rare SCID condition characterized not only by defective lymphoid differentiation but also by a block of myeloid differentiation. Autosomal recessive inheritance is presumed but not strictly proven, owing to the rarity of patients with this syndrome. It is not clear whether some forms of SCID with neutropenia truly represent a different syndrome or whether blocked hemopoiesis could be secondary to persistent viral infection in some cases. Not much is known about the pathogenic mechanisms of the syndrome but that its hematopoietic origin was suggested because it is curable by bone marrow transplantation. Deafness is often found in association with the SCID phenotype. Of note, SCID has been described with cyclic hematopoiesis, which resolves following bone marrow transplantation.

T-CELL IMMUNODEFICIENCIES WITH DETECTABLE T CELLS (COMBINED IMMUNODEFICIENCIES) (TABLE 35.3)

Many immunodeficient patients present with repeated infections in childhood, and occasionally autoimmunity. Immunological tests in these patients may reveal blood T cells in reduced numbers and with poor function. Antibody responses and immunoglobulin levels may also be abnormal. This clinical presentation is at least as frequent as that of typical SCID, and is associated with a large array of distinct syndromes that are far from being fully recognized and understood. This section will therefore cover the known aspects of T-cell immunodeficiencies characterized by the presence of detectable but usually abnormal T cells. This group of disorders is more commonly known as combined immunodeficiencies (CID).

CLINICAL PRESENTATION

Patients with these forms of CID do not usually develop life-threatening infections during the first years of life, but experience a variety of complications that are directly or indirectly caused by immunodeficiency: infections, autoimmunity, allergy and cancer.

In a survey of 25 patients with functional CID, infections occurred in all and were the first clinical manifestation in 22 cases.³⁹ Respiratory tract infections, frequently leading to bronchiectasis and recurrent or protracted diarrhea, are the most frequent complications. Cutaneous and/or mucosal candidiasis, and central nervous system infection of bacterial or viral origin, are not uncommon. Repetition of infections usually leads to failure to thrive, often necessitating parenteral nutrition. About two-thirds of patients develop repeated and/or severe viral infections, especially caused by the herpes group. Autoimmunity is a very frequent complication of CID. It occurs in at least 50% of patients, regardless of the precise diagnosis, at any time during childhood or early adulthood. The autoimmunity is caused mostly by autoantibodies against blood cells (anemia, thrombocytopenia, and neutropenia), although hepatitis, and vasculitis involving the brain and kidney have been observed. Autoimmunity is often severe and tends to relapse, requiring aggressive immunosuppression, which can worsen the immunodeficiency.

The mechanisms of autoimmunity in this setting remain unclear. It is also possible that the processes of negative selection of developing T and B cells and peripheral tolerance are impaired by the immune deficiency, resulting in the expansion of autoimmune clones. In addition, a deficiency in T-regulatory cells producing immunosuppressive cytokines such as IL-10 and TGF- β , can participate in this phenomenon.

Allergic manifestations (eczema, asthma, urticaria, etc.) are also frequent (48% in our series). Elevated serum IgE is a frequent finding in patients with CID. Cancer, and especially lymphomas, are not uncommon as a cause of death in these patients.

The natural outcome in this group of patients is generally poor, with a mean survival of 5–10 years. Causes of death usually include organ failure that is progressively worsened by poor nutritional status and uncontrolled infection by various microorganisms, despite prophylactic use of antibiotics, antifungal therapy and immunoglobulin supplementation. Early BMT is often proposed as the definite treatment, given the almost universal development of organ failure in older patients.

Table 35.3 T-cell deficiencies (combined immunodeficiencies)

Defect	Inheritance	Phenotype	Molecular defect
MHC class II deficiency (Bare lymphocyte syndrome)			
A	AR	Defective exp of MHC class II	Transactivator CIITA
B	AR	"	RFXANK
C	AR	"	RFX5
D	AR	"	RFXAP
CD3 deficiencies

ϵ (hypomorphic)	AR	"	CD3 ϵ
Activation deficiencies			
Low CD8/abnormal CD4	AR		ZAP70
defective Ca ²⁺ flux	AR	Functional T cell ID	ORAI1
CD25 deficiency	AR	Functional T cell ID	CD25
PNP deficiency		Progressive T cell ID	PNP
ADA deficiency (late onset)	AR	Neurological manifestations	
	AR	Progressive T cell ID	ADA
Omenn's syndrome	AR	Activated T cells in skin and gut Oligoclonality	RAG1, RAG2 Artemis, IL7-R α
XL T-cell immunodeficiency	XL	Progressive T cell ID	Mild type IL2R γ of XL SCID

XL, X-linked recessive.

DIAGNOSIS OF CID

The clinical diagnosis of CID is suggested by repeated infections, often associated with allergy and autoimmunity disease. Findings of mild T-cell lymphocytopenia and disturbances in functional T-cell assays (*in vivo* skin tests and *in vitro* proliferative tests in the presence of immunizing antigens) leads to the diagnosis in the absence of an acquired cause, such as HIV infection or malnutrition. An extended phenotype analysis, including enumeration of naïve and memory subpopulations of T cells, CD45RA⁺ and CD45RO⁺, respectively, may be useful for the diagnosis of unclear immunodeficiencies if a cell subset is absent or markedly decreased. Patients with CID may present with hyperimmunoglobulinemia of all isotypes, due to nonspecific polyclonal activation. However, partial hypogammaglobulinemia and a defective antibody response to immunizations are more commonly found.

CID DISEASES

Major histocompatibility complex (MHC) class II deficiency ('bare lymphocyte syndrome')

This is a relatively rare autosomal recessive primary immunodeficiency characterized by a profound defect in the expression of HLA class II molecules. The disease was first described in 1979, since when more than 100 cases have been identified, mostly in patients originating from the

KEY CONCEPTS

QUALITATIVE T-CELL DEFICIENCY

- >> T lymphocytes can be identified in patients, but weak or absent T-cell responses are observed.
- >> B cells are present but respond abnormally because of lack of proper T-cell interaction and cytokine production.
- >> Survival beyond infancy is seen, but infections, autoimmune disease, and cancer produce morbidity and premature demise.
- >> Some defect in surface antigen, activation protein, or cytokine production prevents normal T-cell activity.

Mediterranean area.⁴⁰ Clinical onset occurs in the first year of life, usually with recurrent bronchopulmonary infections and chronic diarrhea. The clinical course is marked by unremitting diarrhea, hepatitis and cholangitis, viral meningoencephalitis and various autoimmune manifestations. The mean age at the time of death is 4 years, often caused by overwhelming viral infections due to either enteroviruses, adenoviruses or herpes viruses. It has recently been recognized, however, that some patients can survive into adulthood with little symptomatology. Diagnosis relies on the absence of HLA DR, DQ, DP and DM molecules at the surface of all cells constitutively expressing HLA class II molecules

(B cells, monocytes, dendritic cells) and at the surface of interferon (IFN)- γ -activated cells (T cells, fibroblasts, etc.). Antigen-specific responses *in vivo* and *in vitro* are absent, whereas allogeneic responses and T-cell numbers are preserved (although CD4 T-cell counts are decreased). There is variable hypogammaglobulinemia, mainly affecting IgA and IgG₂. Antibody production is profoundly defective.⁴¹

Some MHC class II expression has been detected post mortem on medullary cells of children's thymuses and, more importantly, from aborted fetuses. This finding suggests leakiness of the defect (although leakiness in the periphery is uncommon) or the presence of an alternative regulation pattern of MHC class II gene transcription in thymic cells. In any case, this can account for partially preserved T-cell differentiation as well as a capacity for self-/nonself-discrimination. V β element usage by TCRs of residual CD4 T cells was found to be normal, indicating that V β element usage frequency is independent of selection events.

The disease genetically segregates independently of the MHC, which implies that the responsible gene(s) lie(s) outside the MHC and exert(s) a pleiotropic transregulation of MHC class II expression. Fusion experiments between MHC class II⁻ B-cell lines from patients with this immunodeficiency have defined four complementation groups (A, B, C, D) (Table 35.4). The identification of the genetic causes of these four complementation groups has led to a better understanding of MHC class II expression regulation. MHC class II expression is regulated by a proximal promoter region that contains four *cis*-acting DNA elements called the S, X, X2 and Y boxes. RFX, X2BP and NF-Y bind respectively X, X2 and Y boxes (Fig. 35.5).⁴¹ RFX, is expressed ubiquitously and is a heteromeric protein consisting of three elements, RFXAP (p36),⁴² RFX5 (p75)⁴³ and RFXANK (p33)⁴⁴ or RFX-B. In MHC class II deficiency a mutation in either one of the genes has been found. Mutations affecting RFXANK/RFX-B were found in the complementation group B,^{43, 44} with a common deletion observed in patients of north African origin,⁴⁴ of RFX5 in group C,⁴² and of RFXAP in group D.⁴² A defect in any of these proteins leads to the absence of the RFX complex. This situation is associated with nonoccupancy of the MHC class II promoter, as shown by DNase protection assay and *in vivo* footprint experiments (Table 35.4). This indicates that binding of NF-Y and X2BP to box Y and X2 is dependent on the RFX complex showing cooperativity of these transcription factors. The MHC class II tissue specific and inducible expression is under the control of the CIITA *trans*-activator. The *CIITA* gene is transcribed constitutively in B cells, dendritic cells and activated T cells, and in other cells upon stimulation with IFN- γ .⁴¹ Mutation in the *CIITA* encoding gene is responsible for group A of MHC class II deficiency. *CIITA* interacts with the RFX proteins to stabilize the complex and enable class II gene transcription.

TAP-1 and TAP-2 deficiencies

In 1994, de La Salle et al.⁴⁵ reported on two siblings presenting with chronic pneumonia in whom expression of HLA class I molecules was reduced and who exhibited a CD8 lymphopenia. This immunodeficiency phenotype was caused by mutation in the *TAP-2* gene. TAP-1 and TAP-2 proteins compose the HLA class I-associated peptide transporter. The TAP complex transports peptides from the cytosol to the endoplasmic reticulum, where the loading of HLA class I molecule by the peptide occurs. In the absence of the TAP complex, the HLA class I molecules are peptide free and thus unstable. The *Tap-1* and *2* encoding genes are localized on chromosome 6 within the HLA class II gene region.⁴⁶

Table 35.4 Class II deficiency/bare lymphocyte syndrome

Complementation group	Molecular defect	
A	Promoters occupied by DNA-binding proteins	Transactivator CIITA
B	Promoters unoccupied <i>in vivo</i>	RFXANK/RFX-B
C	Promoters unoccupied <i>in vivo</i>	RFX5
D	Promoters unoccupied <i>in vivo</i>	RFXAP

The main clinical manifestations of TAP-1/TAP-2 deficiency are characteristic of an immunodeficiency. They consist of chronic lung infections, often leading in late childhood to bilateral bronchiectasis. Sinusitis and nasal polyposis are also often reported.⁴⁶ The lung manifestations can be a consequence of chronic infection, but necrotizing granulomatous lesions are also present in some cases. In none of the cases was a susceptibility to viral infections such as herpes virus noted.

The diagnosis is based on the reduced (30–100-fold) expression of HLA class I molecules on blood mononuclear cell surfaces. Expression of these molecules is not increased by PHA or IFN- γ stimulation. TcR α/β CD8 lymphopenia may be observed, but does not always occur. An excess of TcR γ/δ -bearing T cells (using more often δ_1 than δ_2) has been described in some cases: these could be autoreactive and participating in the generation of the skin lesions. The number of circulating NK cells is variable between patients, and they may be involved in the pathogenesis of vasculitis as potentially autoreactive NK cells. It has been shown that the cytotoxic activity of CD8 cells against virus-infected targets is preserved. These results suggest that a possible recognition of antigens presented by HLA class I molecules in a TAP-independent manner can occur in these patients.⁴⁷ Humoral immune responses have been found to be normal.

CD3 γ and ζ deficiencies

CID due to CD3 deficiencies is extremely rare. The most prominent feature of CD3 deficiency is the defective expression (1–50% of normal expression) of the CD3/TCR complex on T cells despite normal T-cell numbers. The proportion of either CD8 or CD4 T cell could be low in these patients. In all cases, anti-CD3 monoclonal antibody-induced activation is poor, as judged by cell proliferation, CD25 expression induction and intracellular calcium increase. Antigen-induced proliferation is either low or normal, depending on the antigens tested. Antibody responses to protein antigens after vaccination are normal or only partially affected. However, antibody responses to polysaccharides could be defective.

The clinical manifestations of CD3/TCR deficiency are variable between patients. For example, in a Spanish family, one of two siblings had a severe phenotype whereas the other had no symptoms. The former developed failure to thrive, autoimmunity, protracted diarrhea and fatal pneumonia at 32 months of age. His affected brother had only infrequent respiratory tract infections and no autoimmune manifestations. Mutations in the CD3 γ chain-encoding gene have been found in two patients, one

Fig. 35.5 Promoter region of HLA class II gene in HLA class II expression deficiency. The complex RFX composed of RFXAP, RFX-ANK/B, and RFX5 binds the X box and is stabilized by the transactivator CIITA. Mutations in one of these four components are involved in the four complementation groups of HLA class II deficiency. (From Masternak K, Barras E, Zufferey M, et al. A gene encoding a novel RFX-associated transactivator is mutated in the majority of MHC class II immunodeficiency patients. *Nature Genet* 1998; 20: 273.)

Spanish and one of Turkish origin. In the Turkish case, the parents were first cousins and the mutation was a nucleotide substitution leading to a stop codon. In the Spanish case, a point mutation affected an initiation codon on the paternal allele and a splicing site on the maternal allele. Interestingly, the absence of CD3 γ protein did not completely abolish CD3/TCR expression, which was reduced to 50% of control values. CD8 T-cell counts were reduced in these patients, leading to the suggestion that CD8 interacts with CD3 γ in the antigen recognition unit. More recently, a homozygous mutation of CD3 ζ has been reported in two patients with serious infections that abolished the expression of CD3 ζ chain.^{48,48a} The residual expression of TCR/CD3 complex at the membrane levels was very low (1% of the normal expression) and thus T cells were incapable of activation through the antigen receptor. Surprisingly, in one patient the germline mutation of CD3 ζ was associated with three somatic CD3 ζ mutations in 10% of T cells. All these mutations were located at codon 70, thus restoring normal expression of the T-cell receptor–CD3 complex, which included a ζ chain presenting an amino-acid substitution. However, in spite of this normal expression, no ZAP-70 phosphorylation was detected after TCR/CD3 triggering.⁴⁸

T-cell activation deficiencies (Fig. 35.6)

ZAP-70 deficiency

Several patients with low CD8 T-cell counts have been shown to lack expression of the lymphocyte kinase ZAP-70, resulting in defective T-cell receptor signaling and CD8 thymic selection. This disease results from mutations in the ZAP-70 encoding gene, leading to the absence of the protein.⁴⁹ The absence of peripheral blood CD8 T cells contrasts with normal or elevated counts of CD4 T cells, although they do not respond to T-cell receptor-mediated activation signals. NK cells are found in normal numbers. This immunodeficiency is associated with a low level of serum immunoglobulins and a defect in antibody responses. The phenotype of this immunodeficiency supports the key role of ZAP-70 in downstream signaling upon TCR cross-linking. ZAP-70, once

Fig. 35.6 Schema of T-cell activation deficiencies. Mutations in the CD3 component parts (γ , δ , ϵ , ζ) of the TCR/CD3 complex prevent cell signaling taking place from the cell surface to the cell nucleus. Likewise, mutations in cytoplasmic enzymes (e.g., ZAP-70) inhibit the transmission of cell signals to the cell nucleus via phosphorylation. Many immunodeficiencies have been described that involve this cell signaling pathway. The calcineurin pathway depends on the initial phosphorylation of phospholipase γ (PLC γ), which generates inositol 3P (IP3), responsible for calcium release from endoplasmic reticulum. Calcium depletion of the endoplasmic reticulum or calcium cytosolic increase leads to the opening of a membrane channel.

phosphorylated by kinases such as Lck or Fyn, binds to ITAM motifs on the CD3 complex and then phosphorylates a series of key molecules involved in T-cell activation.

Other T-cell activation immunodeficiencies: Defects in the expression of CD25 and CD8 α

Patients with defective T-cell activation may present with blood lymphocyte counts and phenotypes close to normal ranges. The diagnosis is based on the observation of absent or low proliferation in response to lectins and anti-CD3 antibody. Antigen-induced proliferation is usually absent or low. In these patients, serum Ig levels are either within the normal range or elevated. Ig-restricted heterogeneity has been observed. Antibody responses have been impaired in most cases. Careful examination of T-cell activation pathways has led to finding molecular defects in some cases, such as the report of patient with a mutation in both alleles of the CD25 (IL-2R α chain)-encoding gene. Decreased numbers of peripheral T cells that display poor proliferation capacity characterizes this immunodeficiency.⁵⁰ In a single family, a CD8 T-cell deficiency was described as a consequence of CD8 α gene mutations. Clinical consequences are limited; interestingly, the presence of cytolytic CD4 T cells could be detected.⁵¹

Omenn's syndrome (SCID with hypereosinophilia)

This syndrome is characterized by early onset after birth of diffuse erythroderma associated with pachyderma and alopecia involving the scalp and eyebrows, protracted diarrhea with failure to thrive, and life-threatening infections. There is marked hepatosplenomegaly and lymphadenopathy. Laboratory investigations revealed frequent lymphocytosis and hypereosinophilia. Extensive T-cell infiltration involving the skin (dermis and epidermis) and gut is characteristic of this condition. In contrast, despite enlargement, lymph nodes are essentially devoid of lymphocytes, which are replaced by macrophages. As in the different SCIDs, the thymus is hypoplastic with little lymphoid differentiation.

Blood T cells express activation markers such as CD25 and HLA class II antigens. Interestingly, the T-cell phenotype is usually characterized by the presence of a predominant T-cell subset that differs from patient to patient, i.e., TCR α/β CD4⁺, TCR α/β CD8⁺ TCR α/β CD4⁻ CD8⁻ or TCR γ/δ . All immunoglobulins are barely detectable, with the exception of IgE, which is increased. Circulating B cells are usually undetectable. The presence of a small number of T-cell clones may be observed.⁵² (Fig. 35.7)

The association of the above-mentioned phenotype with typical T-B⁻ SCID in the same families suggested that a common gene mutation could lead either to a SCID or to an Omenn's phenotype. This hypothesis was validated by the identification of hypomorphic *RAG1*/*RAG2* mutations in patients with Omenn's syndrome.¹¹ The hypomorphic mutations of *RAG1/2*, leading to a residual functional activity of the mutated product, could enable the generation of a low number of functional TCR gene rearrangements in the thymus. Peripheral expansion of autoreactive clones toward epithelial antigens is postulated to account for the accumulation of oligoclonal aggressive T cells, mostly in the skin and gut. Because of the low autoimmune regulator (AIRE) expression in the thymus (a possible consequence of thymopoiesis), the autoreactive nature of these clones could be the consequence of defective AIRE-dependent negative selection.⁵³ Omenn's T cells exhibit a

Th2 phenotype, characterized by high-level production of IL-4 and IL-5. This finding explains why there is an eosinophilia and why the residual B cells make only IgE. More, recently Omenn's syndrome has been reported to occur in patients with *Artemis* mutations¹⁴ or *IL7-R α* mutations.⁵⁴

Hypomorphic *RAG-1* mutations have also been found associated with expansion of oligoclonal TCR $\gamma\delta$ T cells in a context of disseminated cytomegalovirus infection and autoimmunity.¹¹ In one case, $\gamma\delta$ T cells were shown to be CMV specific. These observations emphasize the high variability of phenotypic consequences of *RAG1/2* mutations from typical SCID to milder T-cell immunodeficiency, Omenn's syndrome or only $\gamma\delta$ T-cell expansion. It is likely that functional consequences of *RAG1/2* gene mutations, genetic background and environment (infection) interfere and define the clinical consequences. This degree of complexity is likely to be eventually observed for a number of other T-cell immunodeficiencies.

Purine nucleoside phosphorylase (PNP) deficiency

PNP deficiency is a rare cause of CID. To date, fewer than 50 cases have been reported.⁵⁵ PNP deficiency causes a progressive cellular immunodeficiency that is associated in one-third of cases with defective antibody production. Autoimmunity is also found in one-third of patients (autoimmune hemolytic anemia, thrombocytopenia, etc.). About two-thirds of patients develop neurological manifestations that appear to be specific to the disease, and consist of developmental delay, mental retardation, spasticity, or hypotonia and tremor. Diagnosis is based on PNP activity in red cells or lymphocytes in patients with immunodeficiency. Hypouricemia caused by defective transformation of inosine into hypoxanthine can also suggest the diagnosis. BMT is the sole definite therapeutic approach and has been mostly successful.

PNP deficiency is an autosomal recessive disease. So far, all the mutations of the PNP-encoding gene observed in patients – nonsense, missense or splice-site alteration – completely abolish the enzymatic activity.⁵⁵ PNP deficiency is thought to induce CID by depleting deoxynucleotides: the accumulation of dGTP inhibits ribonucleotide reductase, leading to deprivation of dCTP and dTTP and inhibition of DNA synthesis. It is likely that dGTP accumulation is toxic for resting T cells (causing lymphocytopenia) by a distinct but unknown mechanism.

KEY CONCEPTS

T-CELL DEFICIENCY WITH COMBINED FEATURES

- >> Variable T-cell defects are associated with some abnormality of other cell types or organ systems, as in DiGeorge syndrome, cartilage-hair hypoplasia, ataxia telangiectasia.
- >> B-cell function varies according to the state of T-cell function.
- >> Survival beyond infancy is common, but the quality of life may be poor because of progressive T-cell dysfunction and increasing severity of infection, autoimmunity, and premature appearance of malignancy.
- >> Precise molecular defects and their effect on T-cell function are not completely understood.

Fig. 35.8 Facies of child with DiGeorge syndrome. Note micrognathia, low-set ears and short philtrum.

T-CELL DEFICIENCIES WITH ASSOCIATED NON-IMMUNE FEATURES

DIGEORGE SYNDROME

The DiGeorge syndrome (DGS) results from faulty development of the third and fourth branchial arches, which leads to thymic, parathyroid and conotruncal cardiac defects. Facial defects are also found, and include micrognathia, low-set and posteriorly rotated ears, hypertelorism or a short philtrum (Fig. 35.8). Cardiovascular lesions usually consist of an interrupted aortic arch and truncus arteriosus. Mental retardation, suction defect and dysarthry are also common.

Depending on the degree of immunodeficiency, 'complete DGS' with thymic aplasia and very low T-cell counts is different from the more common 'partial DGS' with reduced T-cell counts and mild immunodeficiency. Parathyroid aplasia and conotruncal heart defects can be found with any degree of immunodeficiency. Heterogeneity can also be found in the clinical course, with partial resolution of the T-cell dysfunction. Thymic hypoplasia is found in most patients, but persistent immune dysfunction in only a few. Significant clinical problems secondary to T-cell lymphocytopenia are only observed in a minority of patients, in those who usually have <500 T cell/ μ L of blood. There is thus, a clinical spectrum of presentations, ranging from thymic aplasia with absence of T cells (<1% of DGS cases) to mild or normal T-cell counts. When T-cell counts are normal, patients may be considered in the clinically

overlapping velocardiofacial syndrome, which does not include defective development of the thymus.

DGS is a developmental field defect of the pharyngeal pouches involving neural crest derivatives. Autosomal-dominant inheritance with variable penetrance is observed. Cytogenetic abnormalities are detected in most cases, and include rare mosaic tetraploidy and 10p deletion. More than 90% of patients have a hemizygous deletion of 1.5–3 Mb interval on chromosome 22q11.2 (Fig. 35.9). This specific hemizygosity is also found in the velocardiofacial syndrome. The minimal DiGeorge gene locus has been restricted to 250 kb and includes 24–30 genes. Some of these genes are candidates to explain the complex phenotypes observed in DiGeorge patients. One candidate is *UFD1L*, an ortholog of a yeast gene involved in the degradation of ubiquitinated proteins. Haploinsufficiency of *UFD1L* in a mouse model causes the same congenital heart and craniofacial defects as in DGS.⁵⁶ Of note, one DGS patient carries a monoallelic deletion of exons 1–3 of *UFD1L* as well as of a *CDC45L*, a closely linked gene.⁵⁶ More recently mutations in *TBX1* has been found in two unrelated DGS patients without deletion at 22q11.2.⁵⁷ *TBX1* maps within the DiGeorge region and encodes a T-box transcription factor that is required for the proper development of the heart. Its complete loss in mice causes development defects similar to those seen in DGS patients. Modifier genes, such as *VEGF* which regulates *TBX1* expression, could explain the variability of the phenotype observed in patients.⁵⁸

The most severe immunological form of DGS requires therapeutic intervention for survival. This can be accomplished either through HLA-identical bone marrow transplantation, which can provide expanding mature T cells in the absence of GVHD, or by transplantation of thymic tissue, as shown recently in a small number of patients,⁵⁹ indicating that host-derived hematopoietic cells within the thymus can govern both positive and negative steps of T-cell education.

WISKOTT-ALDRICH SYNDROME

Wiskott–Aldrich syndrome (WAS) is a complex X-linked disorder characterized by an immunodeficiency associated with thrombocytopenia, abnormal platelets and eczema. Its frequency has been estimated at one case per 250 000 live births.⁶⁰

Patients may present with a bleeding tendency that can be apparent as early as in the first few months of life, often as bloody diarrhea. This occurs because of thrombocytopenia secondary to peripheral destruction of platelets, and in most cases splenectomy corrects it. WAS patients have abnormal megakaryocytopoiesis, resulting in a reduction of the mean platelet volume and impaired aggregation. Thrombocytopenia is of variable intensity, but can worsen during infections or because of overt autoimmune antibody production against platelets. Thrombocytopenia relapses can occur, especially in young children (less than 3 years of age). Eczema is frequent, severe, tends to be diffuse, and relapses frequently. Its association with thrombocytopenia and small platelets in young boys is strongly suggestive of WAS.

The immune deficiency in WAS is complex. It is characterized by defective production of antibodies to polysaccharides, increasing the susceptibility of infections by encapsulated organisms such as *Haemophilus influenzae* and *Streptococcus pneumoniae*, with low serum IgM but generally elevated levels of other Ig isotypes.⁶⁰ Worthy of note is that IgM serum levels are often normal or elevated during the first year of life. The T-cell deficiency consists of gradual hypoplasia with a reduction in T-cell counts, especially CD4 T cells, which correlates

Fig. 35.9 Cytogenetic features in immunodeficiencies. **(A)** A 7.14 translocation in ataxia telangiectasia (PHA blasts). **(B)** Centromeric elongation (top) and multimeric chromosomes (bottom) in ICF syndrome. **(C)** Hemizygosities of 22q11 in DiGeorge syndrome as revealed by fluorescence in situ SC111.1 probe (arrows).

with spontaneous cell apoptosis.⁶¹ There is no specific test that is consistently abnormal, although cytotoxic T-cell function is often defective. Nevertheless, the T-cell deficiency can be severe enough to facilitate severe viral infections and some opportunistic infections (e.g., *Pneumocystis jirovecii*).

Autoimmune manifestations are not uncommon in WAS. In addition to the production of autoantibodies to platelets, autoimmune hemolytic anemia and neutropenia can be observed, sometimes in very young children. Severe vasculitis, aneurysm and glomerulonephritis have been described, and require management by aggressive immunosuppression.⁶²

The risk of cancer in WAS patients has been estimated at 2% per year. Lymphomas are the most frequent malignancies. The overall prognosis of WAS remained poor for many years, with a median survival of 5–7 years in 1980. The main cause of death was infection (59%), followed by hemorrhages (27%) and malignancies (5%). This led to the successful introduction of allogeneic BMT as a therapeutic option. BMT from an HLA-identical donor now offers a better than 90% chance of cure.⁶⁰

Genetic segregation studies of WAS in families indicated that there was a single locus mapping to the proximal part of the short arm of the X-chromosome in Xp11-Xp1.3. The X-chromosome inactivation pattern in obligate carriers is nonrandom in all hematopoietic lineages, indicating functional expression of the WAS gene in all cell lineages. In 1994, a novel gene (*WASP*) was isolated⁶³ and mutations of this gene were found in WAS and in isolated X-linked thrombocytopenia (XLT).⁶⁴ The gene product, WASP, is a 53-kDa protein in which several functional domains have been identified: a pleckstrin homology domain in the N-terminal region, a GTPase-binding domain (CRIB motif) and in the C-terminal region a proline-rich domain and a Verprolin/cofilin domain. Mild forms of the disease have been observed in patients with WAS mutations, with few or no infections, mild immunodeficiency, mild

eczema and thrombocytopenia. At this end of the spectrum is XLT. XLT is more frequently associated with missense mutations and typical severe WAS with mutations leading to an absence of the WAS protein.⁶²

Morphological and membrane abnormalities, as well as signal transduction defects, have been described in WAS platelets and lymphocytes. The reduced response of platelets to agonist stimulation and the poor mitogen-induced proliferation by T cells have been shown to be associated with impaired early biochemical events of activation.⁶⁵ All these data suggested a main role of WASP in the cytoskeletal arrangement and the activation pathways. The WASP protein structure is fully coherent with this hypothesis. Defective WASP expression leads to a defective formation of the immunological synapse upon TCR activation. The CRIB motif interacts with the actin-binding protein cdc42, which regulates filopodial and lamellipodial extensions. The proline-rich domain binds SH3-containing proteins such as Grb2 and Fyn, involved in activation events. In addition, a WASP-interacting protein (WIP) and the complex WASP-WIP is able to induce actin polymerization and redistribution in lymphoid cells.⁶²

T-CELL DEFICIENCIES WITH DNA REPAIR DEFECTS

Ataxia-telangiectasia and AT-like disorder

Ataxia-telangiectasia (AT) is an autosomal recessive disease characterized by oculocutaneous telangiectasias and progressive cerebellar ataxia with Purkinje cell degeneration; it is usually an immunodeficiency of IgA, IgE and IgG₂, with a moderate reduction in T-cell counts and responses. AT patients are prone to lymphomas and epithelial cell carcinomas. A hallmark of AT is DNA fragility with abnormal chromosome translocation in lymphocytes, mainly involving TCR and Ig loci and known as illegitimate

recombination. AT cells are abnormally sensitive to ionizing radiation and exhibit radioresistant DNA synthesis.

Patients have IgA and IgG₂ deficiency, which probably accounts for the most frequent (sinopulmonary) infections. There is, however, a T-cell deficiency, because the thymus (at autopsy) is markedly hypoplastic and peripheral T-cell counts are usually decreased. Functional *in vitro* T-cell assays usually reveal mild defects, although T-cell cytotoxicity can be more profoundly affected. Clinical consequences of the T-cell immunodeficiency appear limited: for instance, opportunistic infections are uncommon. Management includes immunoglobulin replacement and prophylaxis antibiotics to prevent and reduce the frequency of infections.

A hallmark of AT is cytogenetic abnormalities, found predominantly in T cells; these consist of chromosomal rearrangements mainly involving 7p14, 7q35, 14q12 and 14q32 (Fig. 35.9). These breakpoints correspond exactly to the respective sites of TCR γ , TCR β , TCR α/δ and immunoglobulin heavy-chain loci. Inversions and translocations result from these chromosome rearrangements. They affect on average 10% of mitoses and form hybrid antigen-receptor genes. The site-specificity of these breaks represents abnormal 'illegitimate' lymphocyte antigen receptor rearrangements, which may explain the gradual decline in T-cell counts. About one in 10 AT patients develops T-cell clones, the proportion of which among peripheral T cells increases with time. These clones are not associated with clinical manifestations and are characterized by unique chromosomal translocations affecting chromosome 14, including a q32 breakpoint proximal to Ig heavy-chain loci. Ultimately, after several years, such clones evolve into T-cell leukemia. Many other breakpoints are also detected in leukemic T cells from AT patients.

Ubiquitous radiation hypersensitivity is another remarkable characteristic of AT. An interesting associated hallmark of the disease is the inability of AT cells to stop DNA replication following γ irradiation. This anomaly is likely to underlie the extreme susceptibility to cancer found in AT patients (200-fold increased risk) and even in AT heterozygotes (fivefold increased risk).

The AT locus has been mapped to chromosome 11q23. The ATM gene encodes a 350 kDa protein containing a functional kinase domain that is homologous to the PI-3 kinase family.⁶⁶ The ATM protein is ubiquitously expressed in all tissues and is present in both the cytosol and the nucleus. Mutations of the *ATM* gene have been found in most AT patients leading to truncated proteins, and missense mutations leading to amino acid substitutions have been reported in association with a milder phenotype.

Interestingly, clinical heterogeneity in AT has been further underlined recently with the description of patients having typical chromosomal translocations, immunodeficiency and lymphomas, but without ataxia or telangiectasia, and patients with peripheral neuropathy and spinal atrophy but without telangiectasia or immunodeficiency.

The function of ATM protein is complex and involves the control of genomic stability. The protein acts as a sensor of radiation-induced DNA damage and induces cell cycle arrest at different checkpoints through multiple steps and protein interactions.⁶⁷ It is involved in the DNA repair process by activating the double-strand break (DSB) repair protein complex hMRE-11/hRad50/Nbs1. Monitoring of DNA integrity is also mediated by radiation-induced association with a histone deacetylase (HDAC1) involved in chromatin structure modification and DNA packaging.⁶⁸ Genomic instability in AT patients probably accounts for premature cell senescence (e.g., Purkinje cells in the cerebellum) and cancer risk.

Mutations in *MRE11* have been reported in three families with AT-like disorder (ATLD), which includes progressive cerebellar degeneration and immunodeficiency, but not ocular telangiectasia. *MRE11* is part of the DSB complex, with DNA exonuclease and endonuclease activity; it senses double-strand damage and promotes the joining of noncomplementary ends.⁶⁹

Nijmegen breakage syndrome (NBS)

Nijmegen breakage syndrome shares some of the characteristics of AT. Common features include similar chromosomal rearrangements in T cells, defective inhibition of DNA synthesis following irradiation, and an immunodeficiency. These patients have no clinical signs of ataxia or telangiectasias. They do, however, have microcephaly and developmental retardation. The immunodeficiency is more severe than in AT, with profound T-cell lymphocytopenia and depressed T-cell responses to mitogens and antigens. Panhypogammaglobulinemia is common. In addition, malignancies are very frequent and appear early in life: five of 14 patients in one series developed lymphomas between 2 and 12 years of age.⁷⁰

The NBS gene has been identified. *NBS1* encodes the nibrin or Nbs1 protein, one member of the hMRE11/Rad50/Nbs1 complex that is activated by ATM to bind and repair double-strand DNA breaks.⁷¹ It is remarkable to observe how the study of three related diseases – AT, ATLD and NBS – has contributed to unravel a complex molecular pathway involved in the control of genomic integrity.

Immunodeficiency, centromeric instability and facial anomalies (ICF syndrome)

The ICF syndrome associates, in a heterogeneous manner, an immunodeficiency and facial anomaly to centromeric chromosome instability. About 20 cases have so far been reported in the literature.⁷² A high rate of consanguinity and occurrence of the syndrome in two siblings strongly supports an autosomal recessive inheritance. Facial anomalies consist of hypertelorism, a flat nasal bridge, epicanthal folds and micrognathia. Mental retardation and malabsorption with failure to thrive have been reported in most cases. However, all these manifestations vary from one patient to another and can be absent. The immune defect is variable and most often characterized by a combined immunodeficiency with quantitative and/or functional T-cell immunodeficiency and panhypogammaglobulinemia, although B cells are normally detectable. However, in some cases only a humoral defect has been observed, and in rare cases typical cytogenetic abnormalities may be found in patients with isolated IgA deficiency.

Cytogenetic studies show typical features characterized by elongation of secondary constriction of chromosomes, which can be associated with multibranched configuration predominantly in chromosomes 1, 9, 16 and less often chromosome 2 (Fig. 35.9).⁷³ These features are detected in activated T cells, less often in EBV-transformed B cells, and rarely in fibroblasts. The anomaly is related to hypomethylation of classic satellites. In females, this hypomethylation also involves the inactive X without notable consequence on X-inactivation. The parent chromosomes are usually normal. Family studies allowed the mapping of the locus to the proximal long arm of chromosome 20. Mutations on both alleles of the DNA methyltransferase *DNMT3B*-encoding gene have been found in nine ICF patients from eight families.⁷⁴ These mutations include missense mutations or insertions causing an aberrant splicing.

Nonhomologous end joining DNA repair defect- DNA ligase IV (LIG4) and Cernunnos deficiencies

In a small number of patients with microcephaly, growth retardation and mild dysmorphic syndrome, a T-cell immunodeficiency of variable intensity, clinically similar to NBS, has been found to be caused by a partial DNA ligase 4 deficiency (also known as LIG4 syndrome).⁷⁵ The severity of the immunodeficiency varies from a 'quasi' SCID to no detectable immunodeficiency, the deficiency commonly detected in a setting of unusual toxicity of chemotherapy and radiation in a leukemic child. DNA ligase IV is involved in the final ligation step of the NHEJ process required for V(D)J recombination of TCR and BCR genes. It is likely that defective DNA LIG4 activity leads to a significantly reduced survival of T- and B-cell precursors, accounting for the immunodeficiency and predisposing to lymphoid malignancies because DNA LIG4 participates in the care of genome integrity.

Six patients exhibiting a similar syndrome associating microcephaly, in utero growth retardation and lymphopenia were found to carry recessive mutations of a newly identified gene called Cernunnos/XLF. Cernunnos has been shown to interact with the XRCC-DNA LIG4 complex involved in the ligation of coding end during the V(D)J recombination process.⁷⁶

Dyskeratosis congenita

This condition is usually inherited as an X-linked recessive disease and is associated with multiple manifestations, including epithelial lesions, predisposition to cancer and progressive aplastic anemia. The most severe forms also include a combined immunodeficiency typically associating the presence of poorly functional T cells together with NK- and B-cell lymphocytopenia. This condition is known as the Hoyeraal-Hreiderosson syndrome.⁷⁷ It is associated with mutations in the dyskerin-encoding gene (*DKC1*), or more rarely with the *TERC* gene in cases with autosomal dominant inheritance, but some cases the molecular basis is not yet understood.⁷⁸ Dyskerin and *TERC* are involved in the telomerase complex necessary for the maintenance of telomeres. When the complex is defective, it leads to premature senescence because of abnormally shortened telomeres.

SHORT-LIMB DWARFISM OR CARTILAGE-HAIR HYPOPLASIA (CHH)

CHH is an autosomal recessive form of metaphyseal chondrodysplasia characterized by short limbs, short stature, hypoplastic hair growth, a variable T-cell deficiency and an erythroid production defect. CHH is common in Finland, and among the Old Order Amish group in the United States. There is extreme variability in the expression of the features of CHH both between and within families. Short stature is, however, a constant feature. There is no clear correlation between the severity of growth failure and that of the immunodeficiency. The immunodeficiency is characterized by lymphopenia of variable magnitude with impaired mitogen-induced T-cell proliferation. The cell cycle of CHH patients' T-cell lines appears to be delayed, with both poor production of IL-2 and a poor response to IL-2. The pathophysiology remains obscure, although a ubiquitous cell-growth defect is plausible. As in other chronic T-cell deficiencies, autoimmunity (erythroblastopenia is frequent) and

cancer are common. Based on a study of 14 Finnish families, the gene was mapped to chromosome 9 and encodes for *RMRP*, which is transcribed into a noncoding RNA associated with the mitochondria RNA-processing endoribonuclease.⁷⁹

Distinct but ill-defined T-cell deficiencies have been reported in some families with other skeletal defects, such as 'Schimke immuno-osseous dysplasia,' which consists of skeletal spondyloepiphyseal dysplasia, short stature, nephropathy, pigmentary skin changes and lymphocytopenia, associated with mutations of the *SMARCA1* gene.⁸⁰

IMMUNODEFICIENCY AND PERIPHERAL MYOPATHY

In three cases of immunodeficiency reported to be associated with peripheral myopathy, TCR-mediated calcium influx was found to be abolished in spite of normal calcium release from intracellular stores.⁸¹ The involvement of ubiquitous calcium release-activated calcium (CRAC) channels in this immunodeficiency was suggested and has been confirmed recently.⁸² A homozygous missense mutation in exon 1 of human *ORAI1* leading to replacement of a highly conserved arginine residue by tryptophan at position 91 was found in two patients from one family. Expression of wild-type *Orai1* in the patients' T cells restored calcium-ion influx triggered by TCR activation.

IMMUNODEFICIENCY ASSOCIATED WITH VENO-OCCLUSIVE DISEASE

In six patients from five families of Lebanese origin living in Australia, a combined functional cell immunodeficiency associated with veno-occlusive disease of the liver has been found to be related to recessive mutations of the *SP110* gene.⁸³ *Sp110* is a protein associated with the PML nuclear body, probably involved in regulating gene transcription. All patients had frequent infections and hypogammaglobulinemia. Other associated features are microcephaly and left atrial endocardial fibrosis.

SCID ASSOCIATED WITH MULTIPLE GASTROINTESTINAL ATRESIA

An absence of T cells or low T-cell counts with very low B-cell counts has been associated with multiple atresias of the gastrointestinal tract. Inheritance is presumed to be autosomal recessive. It is not known whether this is a contiguous-gene syndrome, or whether a factor is involved in both the development of the 'hollow stage' of the gastrointestinal tract and lymphocyte differentiation.

MISCELLANEOUS T-CELL IMMUNODEFICIENCIES

Molecular defects in T cells may cause an immune disorder with clinical manifestations that are not traditionally attributed to cellular immunodeficiency. Two of these conditions, X-linked hyper-IgM and ICOS deficiency, present with hypogammaglobulinemia and are reviewed in detail in Chapter 34. Here we discuss T-cell defects that result in lymphoproliferative disorders and in autoimmune endocrinopathies.

AUTOIMMUNE LYMPHOPROLIFERATIVE SYNDROME (ALPS)

ALPS is a disorder of lymphocyte apoptosis characterized by an increased incidence of autoimmunity, nonmalignant lymphoproliferation, and susceptibility to malignancy. Patients may present early in childhood with lymphadenopathy, splenomegaly and autoimmune cytopenias.⁸⁴ The disease has a wide spectrum, evidenced by the difference of clinical severity among members bearing the same gene mutation within families. Flow cytometry studies in peripheral blood may reveal increased numbers of CD3 T cells, $\alpha\beta^+$, CD4, CD8. Lymphocyte populations show a defect to undergo induced apoptosis *in vitro*, which points to the pathogenesis of the disease. Upon binding of Fas ligand to Fas on the lymphocyte cell surface, signal transduction occur through caspases, leading to the cell and nuclear changes that are characteristic of apoptosis. Defective apoptosis leads to the accumulation of defective or senescent cells, which produce organomegaly and an increased risk of lymphoma, estimated to develop in 10% of patients. The differential diagnosis may include CVID if hypogammaglobulinemia is documented; however, these patients should not present an apoptotic defect. Treatment is directed to reduce organomegaly and resolve cytopenias, and includes steroids, intravenous immunoglobulin and immunosuppressants.⁸⁴ ALPS is discussed in detail in Chapter 14.

X-LINKED PROLIFERATIVE SYNDROME (XLP–PURTILO SYNDROME, DUNCAN DISEASE)

EBV infection can induce uncontrolled B-cell proliferation in patients with profound T-cell deficiencies, such as SCID, or following T cell-depleted BMT. In certain otherwise healthy kindreds, EBV infection was found to have severe consequences such as hepatitis, lymphohistiocytic activation and bone marrow aplasia. In these cases, if not fatal, B-cell lymphoma or agammaglobulinemia may also occur. Antibodies against EBV nuclear antigen, and occasionally to the VCA (viral capsid antigen) and EA (early antigen), are undetectable. These patients are not prone to other severe viral infections. This abnormal X-linked lymphoproliferative-disease gene has been mapped to Xq24-q27 and identified as SH2 domain-encoding. The gene product, SLAM-associated protein (SAP/SH2 D1), was described to interact with the transmembrane receptor SLAM⁸⁵ expressed by T and B cells. SAP can act as a B-cell inhibitor by blocking the recruitment of SH2 domain-containing signal transduction molecule to SLAM, such as the phosphatase SHP-2. The absence of the inhibitor SAP leads to inability to handle the EBV infection. However, a frequent striking feature of XLP is the uncontrolled proliferation of CD8 T cells, much more prominent than the proliferation of EBV-infected B cells. Likewise, it is possible that SAP-deficient CD8 T cells undergo proliferation because of the faulty regulatory function of SAP while being poorly able to kill EBV-infected B cells. In this way, EBV infection would act as a potent trigger of T-cell responses, which are under the control of SAP-associated proteins. NK-cell activity and the EBV-specific CTL activity of SAP-deficient cells are deficient, potentially accounting for the immunodeficiency. Another gene might also be involved in XLP syndrome, as the SAP-encoding gene has been found mutated in only 50–70% of XLP male patients. Moreover, severe EBV infection in girls has also been described.

IMMUNODYSREGULATION, POLYENDOCRINOPATHY AND ENTEROPATHY, X-LINKED (IPEX)

The IPEX syndrome was first observed in eight males of a large family comprising three generations that were related through the females, and who had some or all of the following conditions: diarrhea, eczema, hemolytic anemia, autoimmune diabetes mellitus and hypothyroidism. Also described was increased susceptibility to infections, and patients would usually die in infancy.⁸⁶ Subsequently, similar descriptions of other families with affected male infants were reported, including the additional observations of elevated IgE and eosinophilia, and the successful use of cyclosporine to control the disease.⁸⁷ HLA-identical BMT was shown to correct the immunological abnormalities in one patient; however, he later developed rapidly progressive hemophagocytic syndrome and died. IPEX is caused by mutations in the *FOXP3* gene, a member of a family of transcriptional regulators, and located in chromosome Xp11.23. FoxP3 expression confers the T-regulatory phenotype to CD4 cells. These cells play a major role in the control of autoimmunity and inflammation by decreasing the production of cytokines and other T-cell mediators using a mechanism mediated by cell–cell contact, and by secreting IL-10 to inhibit ongoing immune activation. Bacchetta et al.⁸⁸ have shown that IPEX patients present with normal numbers of regulatory T cells, but they are dysfunctional and unable to suppress autologous effector T cells.

AUTOIMMUNE POLYENDOCRINOPATHY–CANDIDIASIS–ECTODERMAL DYSTROPHY SYNDROME (APECED)

This syndrome is also known as autoimmune polyglandular syndrome I, and is diagnosed when two of the following three findings are present: Addison's disease, hypoparathyroidism and chronic mucocutaneous candidiasis. Other associated conditions are autoimmune hepatitis, juvenile pernicious anemia, alopecia and primary hypogonadism. Thyroid disease and diabetes mellitus are not common. Most patients present with candidiasis before 5 years of age, and almost half develop multiple endocrinopathy. The pathogenesis of the disease involves the development of autoantibodies against multiple targets, including 21-hydroxylase, liver cytochrome p450 (CYP11A), tyrosine phosphatase, tryptophan hydroxylase, and phenylalanine hydroxylase, all enzymes involved in hormone synthesis. The gene responsible for APECED is named 'autoimmune regulator' or *AIRE*, encoding a protein that strongly activates transcription activity, but mutated *AIRE* proteins found in APECED patients have lost this capacity. *AIRE* may induce immune tolerance by enhancing the expression of peripheral-tissue antigens in the thymus, affecting the negative selection of T-effector cells.^{89,90} This gene is located on chromosome 21q22.3 and is expressed in multiple human tissues, essentially the thymus, spleen, lymph nodes and monocytes. The disease is inherited in an autosomal dominant fashion and is most common in the Finnish, Iranian Jews and Sardinian Italians.⁹¹

CHRONIC MUCOCUTANEOUS CANDIDIASIS, WITH OR WITHOUT ENDOCRINOPATHY

Candidal infections can persist on the skin and mucosa in patients with a selective T-cell defect toward *Candida* antigens.⁹² Such susceptibility can be inherited as an autosomal recessive or a dominant trait, and is

sometimes associated with the autoimmune polyendocrinopathy caused by AIRE deficiency. *In vitro* and *in vivo*, T-cell activation by *Candida* antigens is absent as long as the infection persists. Systemic *Candida* infections are rare, and patients can be relatively free of infections if they are receiving antifungal prophylaxis. This disorder is also frequently associated with progressive hypogammaglobulinemia.

Several forms of chronic mucocutaneous candidiasis (CMC) have been described in a few families, although the genetic etiology has remained elusive. An isolated familial CMC, without endocrinopathy, has been reported in families of French-Canadian descent, showing autosomal recessive inheritance and with some predisposition to deep infection.⁹³ Autosomal dominant forms include the CMC restricted to nail infections and with low expression of the ICAM1 adhesion molecule in an Italian family; and a CMC form associated with nonautoimmune hypothyroidism but no other endocrinopathy, described in one family from Alabama.⁹⁴

Inherited disorders of IFN- γ -, IFN- α/β -, and NF- κ B-mediated immunity

Capucine Picard, Jean-Laurent Casanova

36

In the last 10 years, new primary immunodeficiencies (PIDs) affecting interferon (IFN)- γ -mediated immunity, IFN- α/β -mediated immunity, and nuclear factor (NF)- κ B-mediated immunity have been identified. Some of these genetic defects are 'conventional' PIDs, associated with a broad range of infections, but others provide a molecular explanation for severe pediatric infectious diseases previously thought to be idiopathic (Table 36.1). These 'nonconventional' hereditary immunodeficiencies are associated with severe and/or recurrent infections caused by a single family of microorganisms, in contrast to what is observed in 'conventional' PIDs.¹ Standard immunologic explorations, such as leukocyte counts, lymphocyte counts, serological tests for vaccine strains, immunoglobulin levels and complement, are normal in these patients, regardless of whether they are susceptible to one or many infectious agents. Despite the lack of an evident immunological abnormality, infections in these patients are typically severe and often fatal. In this chapter, we describe these new syndromes: disorders of the interleukin (IL)-12-IFN- γ circuit (mutations in the *IFNGR1*, *IFNGR2*, *STAT1*, *IL12B*, *IL12RB1*, *NEMO* genes), associated with the syndrome of mendelian susceptibility to mycobacterial disease (MSMD); combined disorders of IFN- γ - and IFN- α/β -mediated immunity (other mutations in *STAT1*), associated with mycobacterial and viral diseases; and disorders of NF- κ B-mediated immunity, associated with pyogenic bacterial diseases, whether isolated (mutations in *IRAK4*) or associated with mycobacterial and viral disease (other mutations in *NEMO* and mutations in *IKBA*) (Table 36.1).

KEY CONCEPTS

- >> Novel primary immunodeficiencies should be sought in patients with unexplained infectious diseases.
- >> Children with severe infectious diseases should be repeatedly investigated for known and unknown immunodeficiency conditions
- >> The exploration of idiopathic infections leads to the discovery of new PIDs and to a better understanding of immunity against pathogens.

■ MENDELIAN SUSCEPTIBILITY TO MYCOBACTERIAL DISEASE AND INHERITED DISORDERS OF THE IL-12-IFN- γ CIRCUIT ■

Inherited disorders of the IL-12/23-IFN- γ circuit are associated with a selective susceptibility to weakly pathogenic mycobacteria and *Salmonella* (mendelian susceptibility to mycobacterial diseases, MSMD, Online Mendelian Inheritance in Man [OMIM] number 209950) (Fig. 36.1).² These PIDs are caused by mutations in six genes involved in IFN- γ -mediated immunity: *IFNGR1* and *IFNGR2*, encoding the two chains of the receptor for IFN- γ , a pleiotropic cytokine secreted by NK and T cells; *STAT1*, encoding a molecule essential to the IFN- γ R signaling pathway; *IL12B*, encoding the p40 subunit of IL-12 and IL-23, IFN- γ -inducing cytokines secreted by macrophages and dendritic cells; *IL12RB1*, encoding the β_1 chain of the receptor for IL-12 and IL-23, which is expressed on NK and T cells;³ and *NEMO*, encoding NF- κ B essential modulator (NEMO), which is involved in the CD40-dependent induction of IL-12. *NEMO* is X-linked, whereas the other five genes are autosomal. All known mutations in *IFNGR1*, *IFNGR2*, *IL12B*, and *IL12RB1* are associated with MSMD. In contrast, some mutations in *STAT1* and most mutations in *NEMO* are associated with a much broader range of infectious diseases (see below). The molecular and clinical features of MSMD have recently been reviewed.^{4,5}

COMPLETE IFN- γ RECEPTOR 1 DEFICIENCY

Complete IFN- γ receptor 1 (IFN- γ R1) deficiency (OMIM 107470) is caused by recessive null *IFNGR1* mutations precluding the expression of IFN- γ R1 on the cell surface^{6,7} or recognition of the ligand IFN- γ by surface-expressed receptors.⁸ Affected patients therefore fail to respond to IFN- γ both *in vitro* and *in vivo* and have high serum IFN- γ concentrations after infection. So far 24 such patients have been reported.³ All known patients suffered from disseminated infections caused by environmental mycobacteria (EM), notably rapidly growing species, and/or

¹One PD IFNGR1-deficient patient presented one episode of Histoplasma capsulatum infection.

²One IL12RB1-deficient patient presented one episode of Paracoccidioides brasiliensi infection.

bacille Calmette–Guérin (BCG) vaccines, with impaired granuloma formation (Fig. 36.2A).⁹ Infections began early, often before the age of 3 years. A few of these patients presented nontyphoidal salmonellosis and one presented with recurrent invasive infection caused by *Listeria monocytogenes*.⁹ Three patients had respiratory viral infections and one had a fatal human herpes virus-8-driven Kaposi's sarcoma.⁹

Multiple antibiotics against mycobacteria should be administered without interruption. Vaccination with live BCG is contraindicated. The prognosis is very poor, with only 25% of patients surviving to the age of 15 years without hematopoietic stem cell transplantation (HSCT).^{9,10} HSCT, preferably

once mycobacterial disease is under control, is the only curative treatment for these patients, but has proved to be associated with an unusually high rate of graft rejection, making transplantation particularly difficult.

COMPLETE IFN- γ RECEPTOR 2 DEFICIENCY

Six children with complete IFN- γ R2 signaling chain deficiency (OMIM 147569) have also been reported.^{11–13} Mutations in the *IFNGR2* gene encoding IFN- γ R2 lead to a complete loss of cellular responsiveness to IFN- γ , whether due to a lack of receptor expression^{3,13} or to the surface expression of nonfunctional receptors.¹³ Three of these children have the same *IFNGR2* missense mutation associated with the surface expression of nonfunctional IFN- γ R2 chains.¹³ This missense mutation creates a novel consensus site for *N*-glycosylation and defines a new and unexpectedly large class of human pathological mutations, designated 'gain-of-glycosylation' mutations.¹³ All children with complete IFN- γ R2 deficiency had severe, early-onset infections due to environmental mycobacteria and/or BCG, all requiring continuous multidrug therapy.^{3,13} No mature granulomas were observed (Fig. 36.2A). Three of these patients also had cytomegalovirus infection. Two patients underwent HSCT, which was successful in one case. Two of the other four patients died of disseminated mycobacterial infection at the age of 5 years and the remaining two are currently on antibiotic therapy at the ages of 3 and 9 years, respectively.

Multiple antibiotics against mycobacteria should be administered without interruption. Vaccination with live BCG is contraindicated. These patients should therefore also be considered candidates for HSCT. Overall,

THERAPEUTIC PRINCIPLES FOR MSMD PATIENTS

- >> Vaccination with live BCG is contraindicated.
- >> Multiple antibiotics against mycobacteria should be administered without interruption in patients with complete IFN- γ R1 or IFN- γ R2 deficiency.
- >> Anti-mycobacterial antibiotics may be associated with IFN- γ injections in selected patients with partial IFN- γ R1 or IFN- γ R2 deficiency, complete IL-12p40 and IL12RB1 deficiency.
- >> HSCT should be considered in selected patients with complete IFN- γ R1 or IFN- γ R2 deficiency.

Fig. 36.1 Genetic etiologies of mendelian susceptibility to mycobacterial infection. IL-12 is secreted principally by the phagocytes and dendritic cells and binds to a heterodimeric receptor consisting of β_1 and β_2 chains, which is expressed specifically on NK and T lymphocytes. IFN- γ is secreted by NK and T lymphocytes and binds to a ubiquitous receptor made of two chains, a ligand-binding (IFN- γ R1) and a signaling-associated chain (IFN- γ R2). Stat-1 is phosphorylated in response to IFN- γ and is translocated to the nucleus as a homodimer. NEMO is a regulatory protein in the NF- κ B pathway. The engagement of CD40 signaling via the NF- κ B pathway is important for IL-12 production and for protective immunity against mycobacterial infection. The six molecules shown in red have been found to be mutated in certain patients with severe mycobacterial infection.

the immunological features of IFN- γ R2-deficient patients are essentially indistinguishable from those with complete IFN- γ R1 deficiency. Thus, like null recessive *IFNGR1* mutations, null recessive *IFNGR2* mutations cause susceptibility to early-onset, recurrent, multiple, and life-threatening mycobacterial infections with impaired granuloma formation.

PARTIAL RECESSIVE IFN- γ R1 AND IFN- γ R2 DEFICIENCIES

Three patients from two unrelated kindreds having recessive partial IFN- γ R1 deficiency (OMIM 107470) have been reported.¹⁵ A mutation causing an amino-acid substitution in the extracellular domain was identified and the encoded receptor was detected with specific antibodies at the cell surface. The cells of the patients responded only to high concentrations of IFN- γ . One of these children had disseminated BCG and *Salmonella enteritidis* infections with a favorable outcome. His sister, who had not been vaccinated with BCG, had curable symptomatic primary tuberculosis. The third, unrelated, patient had received BCG without complications in infancy and had disseminated *Mycobacterium avium* infection with a favorable outcome at the age of 20 years. These patients had well-circumscribed and well-differentiated tuberculoid granulomas (Fig. 36.2B). These patients are currently 20, 23 and 27 years old, respectively, and have no ongoing treatment. One patient with recessive partial IFN- γ R2 deficiency (OMIM 147569) has also been reported.³ A homozygous nucleotide substitution was found in *IFNGR2*, resulting in a single amino-acid substitution in the extracellular domain. The young adult patient concerned had presented BCG and *M. abscessus* infections and is now well at 25 years of age. Thus, a diagnosis of recessive partial IFN- γ R1 or IFN- γ R2 deficiency should be considered in children and adults with mycobacterial and *Salmonella* infections with a mild clinical and histological phenotype. For these patients, anti-mycobacterial treatment can be stopped, but not before 1 year has elapsed after the control of infection. Patients should then be closely followed.

PARTIAL DOMINANT IFN- γ R1 DEFICIENCY

Patients from 28 unrelated kindreds were found to have a dominant form of partial IFN- γ R1 deficiency (OMIM 107470).^{3,15} These patients have a heterozygous small frameshift deletion in *IFNGR1*, downstream from the segment encoding the transmembrane domain, but upstream from the recycling motif and Jak-1 and Stat-1 docking sites. This heterozygous mutation is therefore loss-of-function and dominant negative and decreases (but does not abolish) cellular responses to IFN- γ in heterozygous cells and patients. A total of 50 patients with this condition have been identified, most bearing the same 818del4 mutation that defined the first hotspot for small deletions. The clinical phenotype is characterized by EM and BCG infections, often affecting the bones.⁹ A diagnosis of mycobacterial osteomyelitis is highly suggestive of dominant IFN- γ R1 deficiency.⁹ Only two patients have presented nontyphoid salmonellosis disease, and one has presented one episode of infection caused by *Histoplasma capsulatum*. Eight of these patients are asymptomatic, but two died of disseminated mycobacterial infection at the ages of 17 and 27 years, respectively. Most have had no prophylactic treatment.

Anti-mycobacterial treatment could be combined with IFN- γ injection in cases of disseminated infection. Antibiotics can be stopped once the infection has been controlled. Vaccination with live BCG is contraindicated. The clinical outcome of patients with partial dominant IFN- γ R1 deficiency, like that of patients with partial recessive IFN- γ R1 and IFN- γ R2 deficiencies, is much better than that of children with complete IFN- γ R deficiency, because there is some residual IFN- γ signaling. There is therefore a strict correlation between *IFNGR1* genotype, cellular phenotype, and clinical phenotype.⁹

IL-12 p40 DEFICIENCY

Twenty patients with complete recessive IL-12p40 deficiency (OMIM 161561) have been reported.^{3,16} The mutations in *IL12B* concerned are small insertions or large deletions. Two founder mutational events have

Fig. 36.2 Two types of granuloma. **(A)** The lepromatous-like type consisted of poorly defined, poorly differentiated granulomas, with few, if any giant cells and lymphocytes, but widespread macrophages loaded with acid-fast bacilli. **(B)** The tuberculoid type consisted of well-circumscribed and well-differentiated granulomas, with epithelioid and multinucleated giant cells containing very few acid-fast rods, surrounded by lymphocytes and fibrosis, occasionally with central caseous necrosis.

been identified in four kindreds from Saudi Arabia and in two kindreds from the Indian subcontinent. Children with this deficiency produce abnormally low levels of IFN- γ , due to a lack of stimulation through IL-12. This defect can be partially corrected, in a dose-dependent manner, with exogenous recombinant IL-12.³ All children inoculated with live BCG vaccine developed clinical infection, two children had infection caused by EM, and one had an infection caused by *M. tuberculosis*. Six patients presented nontyphoid salmonellosis and one presented with a single episode of infection caused by *Nocardia asteroides*, an acid-fast

agent closely related to *Mycobacterium*.³ One of these children is asymptomatic, but six died of infection between the ages of 2 and 11 years.³ The survivors are currently well and aged between 6 and 29 years. Most have had no prophylactic treatment.

Anti-mycobacterial treatment can be combined with IFN- γ injection in cases of disseminated infection. Antibiotics can be stopped, but not before 1 year has elapsed after control of the infection. Granuloma formation is preserved, but may be multibacillary in these patients (Fig. 36.2B). Thus, a diagnosis of IL-12p40 deficiency should be considered in children and adults with mycobacterial and *Salmonella* infections having a mild clinical and histological phenotype. Vaccination of these patients with live BCG is contraindicated.

IL-12R β 1 DEFICIENCY

Fifty-nine patients with recessive complete IL-12 receptor β 1 (IL-12R β 1) deficiency (OMIM 601604), with no cellular expression^{3,17} and one patient with a complete recessive form in which the affected receptor was expressed have been reported.³ The cellular phenotype of IL-12R β 1-deficient patients is a lack of response of NK and T lymphocytes to IL-12 and IL-23, with low levels of IFN- γ production. The clinical phenotype is characterized by EM/BCG infections, with half the patients also presenting with nontyphoid salmonellosis.³ Twenty-nine of the 40 children inoculated with live BCG vaccine developed clinical infection, 12 children had infections caused by EM, and three had infections caused by *M. tuberculosis*.³ The low penetrance for the case-definition phenotype of BCG/EM disease led to the discovery of tuberculosis as the sole infectious phenotype in several patients,¹⁸ providing the first cases of mendelian predisposition to tuberculosis. Twenty-eight patients presented nontyphoid salmonellosis and one presented with a single episode of infection caused by *Paracoccidioides brasiliensis*. Five of these patients are asymptomatic, but 10 died of mycobacterial or *Salmonella* infection before the age of 8 years. The survivors are currently well and aged between 2 and 34 years. Most have had no prophylactic treatment.

Infections can be treated with antibiotics and IFN- γ . Vaccination with live BCG is contraindicated. The prognosis is good for patients with IL12-R β 1 deficiency, partly owing to the low clinical penetrance of primary mycobacterial infection, the favorable response of infections to treatment, and the rarity of recurrent or multiple mycobacterial infections. Indeed, children with primary mycobacterial disease can mount a fully protective immune response against a secondary mycobacterial disease. However, the high incidence of recurrent salmonellosis in these patients suggests that IL-12 is required for both primary and secondary immunity against *Salmonella*.

PARTIAL STAT-1 DEFICIENCY

Four kindreds with heterozygous mutations in *STAT1* causing partial dominant Stat-1 deficiency (OMIM 600555) have been described.¹⁹⁻²¹ Stat-1 is a critical transducer of IFN-mediated signals, either as Stat-1 homodimers – designated γ -activating factor (GAF) – or as Stat-1/Stat-2/IRF-9 trimers, known as interferon-stimulated γ factor 3 (ISGF3) (Fig. 36.3). These heterozygous *STAT1* mutations reduce the cellular response to IFN- γ , but not that to IFN- α . Indeed, the *STAT1* mutations found are loss-of-function for the IFN- γ -induced GAF activation and IFN- α/β -induced ISGF3 activation phenotypes, but are dominant for one phenotype (GAF) and recessive for the other (i.e., ISGF3) in heterozygous cells. Clinically, two patients suffered from disseminated BCG infection with tuberculoid

Fig. 36.3 STAT-1 pathway. The binding of homodimeric IFN- γ to its tetrameric receptor leads to the activation of constitutively associated Jak-1 and Jak-2, which then phosphorylate tyrosine residues in the intracellular part of IFN- γ R1. Upon IFN- γ stimulation, unphosphorylated Stat-1 molecules are directly recruited to IFN- γ R1 docking sites. They are then phosphorylated and released into the cytosol as phosphorylated Stat-1 homodimers, which form γ -activating factors (GAF), which are translocated to the nucleus. GAF binds γ -activating sequences (GAS) present in the promoters of target genes. Following monomeric IFN- α/β stimulation, Stat-2 is recruited to the phosphorylated IFN- α R1 chain of the heterodimeric IFN- α R and is itself also phosphorylated by Jak-1 and Tyk-2. This leads to the phosphorylated Stat-2-mediated recruitment of Stat-1, which is then phosphorylated. Active phosphorylated Stat-1/Stat-2 heterodimers are released into the cytosol and translocated to the nucleus with IRF-9 to form interferon-stimulated genes factor-3 (ISGF-3) heterotrimer. ISGF-3 binds IFN- α/β sequence response elements (ISRE) in the promoters of target genes via the DNA-binding domains of Stat-1 and IRF-9. In humans, recessive complete Stat-1 deficiency results in impaired responses to both IFN- γ and IFN- α/β . It is associated with a specific syndrome, different from MSMD, of susceptibility to both mycobacteria (impaired IFN- γ -mediated immunity) and viruses (impaired IFN- α/β -mediated immunity).

granulomas, one suffered from local BCG infection, and two others had disseminated *M. avium* infection. The other five patients are asymptomatic. All patients are currently well and aged between 3 and 38 years.

Anti-mycobacterial treatment can be stopped, but not before 1 year has elapsed after control of the infection. Vaccination with live BCG is contraindicated. Observations of affected patients suggest that Stat-1 and GAF are required for human IFN- γ -mediated mycobacterial immunity. In conclusion, patients with partial Stat-1 deficiency have clinical and cellular phenotypes (i.e., susceptibility to mycobacterial disease and impaired GAF activation) similar to those of patients with partial IFN- γ R deficiency. These patients should be treated in a similar manner.

NEMO DEFICIENCY (XR-MSMD)

An X-linked recessive form of MSMD (XR-MSMD) was clinically described in 1996,²² and two neighboring mutations (E315A and R319Q) in NEMO were recently discovered in three unrelated kindreds with XR-MSMD.²³ These two missense mutations, which affect two neighboring residues in the leucine zipper domain that normally form a salt bridge, are responsible only for impairing the CD40-triggered induction of IL-12 production by monocyte-derived cells upon stimulation with CD40L-expressing T cells. Four maternally related male family members in two successive generations presented *M. avium* infection and the other two, unrelated, patients suffered from mycobacterial disease. These patients had a purely infectious phenotype, with no sign of anhidrotic ectodermal dysplasia (EDA), with the exception of conical deciduous incisors in one child. The patients are currently well and aged between 8 and 57 years. It is not clear whether anti-mycobacterial treatment can be stopped once the infection has been controlled or when, as the six patients seem to have had different clinical outcomes. Vaccination with live BCG is contraindicated. These two mutations, responsible for impaired T cell-dependent IL-12 production, thus account for the observed susceptibility to mycobacteria. The MSMD-causing mutations in the NEMO leucine zipper domain define the first genetic etiology of X-linked recessive MSMD.²³

INHERITED DISORDERS OF IFN- γ - AND IFN- α/β -MEDIATED IMMUNITY

COMPLETE STAT-1 DEFICIENCY

Three children from three unrelated kindreds with complete Stat-1 deficiency (OMIM 600555) have also been reported.²⁴ These patients carried homozygous mutations, which completely abolished the cellular responses to both IFN- γ and IFN- α/β . All patients had disseminated BCG disease. One patient died of recurrent encephalitis caused by herpes simplex virus, a second died of a nondocumented illness thought to be viral in origin, and the third died 3 months after HSCT, from Epstein-Barr virus lymphoproliferative disorder.²⁴ Recent data indicate that two other children with complete Stat-1 deficiency died of unknown viral diseases, in the course of disseminated infection with BCG (Chappier, unpublished data). The outcome of viral illnesses in children with complete Stat-1 deficiency suggests that the Stat-1-dependent response to human IFN- α/β is necessary for viral immunity. Patients with complete Stat-1 deficiency had multiple, severe, early-onset viral infections.

Multiple antibiotics against mycobacteria, and possibly antiviral treatment directed against herpes viruses, should be administered without interruption and these patients should be considered for HSCT. Vaccination with live BCG is contraindicated.

Complete Stat-1 deficiency defines a severe innate immunodeficiency that should be considered in infants and children with severe infectious diseases, notably (but not exclusively) mycobacterial and viral diseases. Other children with viral and bacterial diseases were recently found to show an impaired cellular response to both IFN- γ and IFN- α/β , indicating that the group of disorders affecting both types of IFN-mediated immunity is likely to expand (unpublished data). Milder forms of Stat-1 deficiency should therefore be considered in children with a milder clinical course than those with complete Stat-1 deficiency.

Fig. 36.4 Genetic defect of the NF-κB pathway. The NEMO-NF-κB signaling pathway is used by several groups of developmental receptors (EDAR, RANK and VEGFR) and by several groups of immune receptors (antigen receptors (TCR and BCR), members of the TNF receptor superfamily (CD40 and TNFR), and the members of the TIR superfamily). The three proteins of the NF-κB pathway (IRAK-4, NEMO, IκBα) responsible for the primary immunodeficiency are shown in red. In IRAK-4-deficient patients, TIR superfamily-induced MAPK kinase activation is also abolished.

INHERITED DISORDERS OF NF-κB-MEDIATED IMMUNITY

This group of inherited disorders leads to impaired NF-κB signaling and strong susceptibility to pyogenic bacteria. The affected patients bear mutations in *NEMO*, *IKBA*, or *IRAK4* (Fig. 36.4).²⁵ Patients with anhidrotic ectodermal dysplasia with immunodeficiency (EDA-ID) syndrome carry either X-linked recessive hypomorphic mutations in *NEMO* or autosomal dominant hypermorphic mutations in *IKBA*. Other patients with autosomal recessive amorphic mutations in *IRAK4* present a more restricted, purely immunological defect, with specific impairment of the Toll and interleukin-1 receptor (TIR)-interleukin receptor-associated kinase (IRAK) signaling pathway.²⁵ Diverse mutations have been found in *NEMO*, associated with a variety of cellular and clinical phenotypes (see above and below). A single type of *IKBA* mutation was found in two unrelated kindreds. All known mutations in *IRAK4* are recessive and loss-of-function, and only one cellular phenotype has been identified to date. Patients with EDA-ID and mutations in *NEMO* or *IKBA* are susceptible to multiple infectious agents, including pyogenic bacteria, mycobacteria and viruses. In contrast, patients with IRAK-4 deficiency seem to be specifically prone to pyogenic bacterial diseases, in particular pneumococcal and staphylococcal diseases.

NEMO DEFICIENCY

X-linked anhidrotic ectodermal dysplasia with immunodeficiency (XL-EDA-ID) is a rare primary immunodeficiency (OMIM 300291). To date, 52 patients with XL-EDA-ID have been reported.²⁵⁻²⁷ Patients with XL-EDA-ID carry hypomorphic mutations in the gene encoding NEMO, a protein essential for activation of the ubiquitous transcription factor NF-κB. X-linked dominant loss-of-function mutations in NEMO are lethal in utero in males and are associated with incontinentia pigmenti in girls.²⁵ In the immunologic work-up of patients with EDA-ID, the only known consistent abnormality is a lack of serum antibodies against carbohydrates, which has been found in most patients reported.²⁵ Some patients have hyper-IgM syndrome and a few have NK-cell abnormalities.²⁵ Most patients bearing hemizygous *NEMO* mutations show weak blood cellular responses to TNF-α. EDA-ID is characterized by hypohidrosis, widely spaced cone- or peg-shaped teeth, and hypotrichosis (Fig. 36.5). However, the range of clinical manifestations appears to be broad, from both developmental and infectious standpoints. Two patients carrying the X420W mutation had osteopetrosis and lymphedema (defining XL-OL-EDA-ID).²⁵ In contrast, some children had an exclusively infectious phenotype, with no sign of EDA. The infectious phenotype is characterized mostly by infections due to encapsulated pyogenic bacteria, such as *Haemophilus influenzae* and *Streptococcus pneumoniae*. Infections caused by weakly pathogenic microorganisms, such as *M. avium* and *M. kansasii*, have also been diagnosed in patients. Other infectious diseases include salmonellosis, pneumocystosis, and viral illnesses caused by herpes simplex virus and cytomegalovirus have been reported. Infectious episodes were marked by a poor clinical and biological inflammatory response. Half the patients with EDA-ID died from invasive infection, demonstrating the severity of this disorder. Thus, NEMO deficiency is a disorder in which a PID may or may not be associated with developmental abnormalities.

All patients should receive monthly prophylactic administrations of intravenous immunoglobulins (IVIG). Prophylactic trimethoprim-sulfamethazole and/or penicillin V should also be considered, along with an intensive vaccination program, including conjugated and nonconjugated vaccines against encapsulated bacteria (pneumococcus, *H. influenzae*, meningococcus). Vaccination with live BCG is contraindicated. Patients with a severe infectious phenotype should be considered for HSCT.

THERAPEUTIC PRINCIPLES FOR INHERITED DISORDERS OF NF-κB-MEDIATED IMMUNITY

- >> All patients should receive conjugated and nonconjugated vaccines against encapsulated bacteria (pneumococcus, *H. influenzae*, meningococcus).
- >> Prophylactic trimethoprim-sulfamethazole and penicillin should also be administered.
- >> Monthly prophylactic administrations of intravenous immunoglobulins (IVIG) should be considered in selected patients.
- >> HSCT should be considered in selected patients with NEMO deficiency.

Fig. 36.5 Two patients with EDA-ID, one presented widely spaced cone- or peg-shaped teeth and the second with conical incisors.

The NEMO–NF- κ B signaling pathway is used by several groups of developmental receptors (EDAR, RANK and VEGFR) and several groups of immune receptors (antigen receptors (TCR and BCR), members of the TNF receptor superfamily (CD40 and TFNR), and members of the TIR superfamily). Clinical variability results from differences in the impact of the various hypomorphic mutations in this pathway. However, the variability of the infectious phenotype seems to parallel, and may be correlated with, the variability of the immunological phenotype.

I κ B α DEFICIENCY

One patient with an autosomal dominant (AD) form of EDA-ID was initially reported,²⁸ followed by a child and his father a year later.²⁹ Patients with AD-EDA-ID carried the same missense mutation (S32I) in *IKBA*, encoding an inhibitor of NF- κ B (OMIM 164008). The father of the second patient has the same mutation, but displays complex mosaicism.²⁹ All patients were heterozygous for this mutation, which is gain-of-function/hypermorphic as it prevents the phosphorylation and degradation of I κ B α , increasing the inhibitory capacity of this molecule. The mutant allele thus exerts a dominant-negative effect over the wild-type allele. Interestingly, the father of the second patient presented a milder clinical and immunological phenotype, probably owing to the complex mosaicism.²⁹ Both children had a lack of memory T cells and an impaired T-cell response to both antigenic and CD3 mitogenic stimulation *in vitro*. They also displayed hyper-IgM syndrome and had the EDA phenotype. From the age of 2 months onwards, they suffered from recurrent opportunistic infections and chronic diarrhea caused by pyogenic bacteria, *Pneumocystis jirovecii* and virus. They also failed to thrive. The two children were treated by HSCT at the ages of 1 and 2 1/2 years, respectively. The father of the second child suffered from recurrent *Salmonella typhimurium* infection. Thus, a diagnosis of I κ B α

deficiency should be considered in children with EDA and severe immunodeficiency with impaired T-cell immunity.

IL-1 RECEPTOR-ASSOCIATED KINASE-4 DEFICIENCY

Inherited interleukin-1 receptor-associated kinase-4 (IRAK-4) deficiency (OMIM 607676) is an autosomal recessive disorder first described in three unrelated patients.³⁰ Nineteen other patients have since been identified³ (Casanova, unpublished data). All but one of the causal mutations concern the kinase domain of the protein (missense mutations and small insertions). The blood cells of the patients fail to produce proinflammatory cytokines upon stimulation by all known Toll-like receptor (TLR) agonists, IL-1 β and IL-18. Clinically, IRAK-4-deficient patients suffer from recurrent infections caused by pyogenic bacteria, mostly Gram-positive, with little or no fever and inflammatory responses. The leading pathogen responsible for infections in these patients is *S. pneumoniae*, which was found in 21 of 22 patients with proven IRAK-4 deficiency and caused bloodborne invasive disease (septicemia, meningitis, or arthritis). The second most frequently detected infectious organism is *S. aureus*, often responsible for skin infections, but occasionally also for infection of the liver or septicemia. Invasive disease caused by Gram-negative bacteria was diagnosed in these patients on only three occasions (*Pseudomonas aeruginosa*, *Neisseria meningitidis* and *Shigella sonnei*). All sudden invasive infections occurred before the age of 10 years. IRAK-4 deficiency is a life-threatening disease, resulting in the deaths of nine of the 22 known patients, all of whom died before the age of 8 years. There is an overall trend towards improvement with age, as shown by the two adult patients doing well with no treatment at the ages of 24 and 33 years, respectively.

All IRAK-4-deficient patients should receive monthly prophylactic administrations of IVIG until the age of at least 10 years. Prophylactic trimethoprim-sulfamethazole and/or penicillin V should also be considered, along with an intensive vaccination program, including conjugated and nonconjugated vaccines against encapsulated bacteria (pneumococcus, *H. influenzae*, meningococcus). A diagnosis of IRAK-4 deficiency should be considered in children presenting with recurrent pyogenic infection with poor inflammatory responses.

CONCLUSION

An understanding of the molecular basis of these new immunodeficiencies affecting the innate immune responses mediated by IFN- γ , IFN- α/β , or NF- κ B, has provided detailed insight into the pathogenesis of infections in affected patients, paving the way for genetic counseling and rational treatment design. New PIDs should be sought in patients with unexplained infectious diseases, whether caused by a single or multiple infectious agents, even if all standard immunological explorations are normal. Interestingly, even common infectious diseases, such as tuberculosis, invasive pneumococcal disease and herpes encephalitis, may be favored by mendelian immune disorders. The discovery of many new PIDs is an exciting perspective, not only increasing our understanding of immunity to pathogens, but also benefiting patients. It is thought that most children with severe infectious diseases probably suffer from an underlying PID,³¹ and should be repeatedly investigated for known and unknown immunodeficiency conditions.

ACKNOWLEDGMENTS

We thank Laurent Abel and Christine Bodemer, our laboratory colleagues, our collaborators at Hospital Necker-Enfants Malades and elsewhere, and our patients and families for their assistance in making possible the studies contained in this chapter. This work was supported by the Foundation BNP-Paribas, the Foundation Schlumberger, and EU grant number QLK2-CT-2002-00846. JLC is an International Scholar of the Howard Hughes Medical Institute.

HIV infection and acquired immunodeficiency syndrome

Christopher S. Baliga, Mary E. Paul, Javier Chinen,
William T. Shearer

37

The human immunodeficiency virus (HIV) has proven to be a formidable adversary for both the human immune system and medical science. After 25 years of intense research, HIV infection is still one of the most-studied infectious diseases. The clinical care for the disease caused by HIV infection, the acquired immunodeficiency syndrome (AIDS), has particular complexities due to the compromise of the immune system and the side effects of the anti-HIV drugs; consequently, it has now matured into a clinical discipline in its own right. The accumulated knowledge of this disease and its pathogenesis has led to the rapid development of effective, albeit expensive, treatment drug regimens. These anti-HIV drug therapies do not eradicate HIV infection; however, they have proven to prolong the survival of HIV-infected patients significantly. Ongoing research focuses on the discovery of new anti-HIV drugs and alternative approaches to control the spread of HIV infection, such as novel vaccines and topical microbicides.

■ EPIDEMIOLOGY ■

GLOBAL PERSPECTIVE

The face of the HIV pandemic initially varied depending on the geographic area, reflecting the different groups of people at risk in which this new infection was first described. Many of the stereotypes of the “typical” HIV-infected patient resulted from these initial reports: male homosexuals in the developed world, intravenous drug users (IDUs) in Eastern Europe, and commercial sex workers in Asia and Africa. These early descriptions do not accurately reflect today’s pandemic. As of December 2006, there were about 40 million people living with HIV infection worldwide (Fig. 37.1). Of these, 43% were women and 2.3 million were children.¹ An estimated 2.9 million people died from AIDS in 2006, with more than 25 million deaths since 1981.

The developing world continues to bear the brunt of the epidemic. Sub-Saharan Africa alone is home to over two-thirds of all HIV-infected individuals and, importantly, 77% of all the HIV-infected women. Data from prenatal clinics in sub-Saharan Africa show that, in

six countries – Botswana, Lesotho, Namibia, South Africa, Swaziland, and Zimbabwe – over 20% of pregnant women are infected with HIV. In Botswana and Swaziland, the incidence levels are closer to 30%. It is important to realize that the people contracting and dying from HIV infection are the young, economically productive members of society. In South Africa, the mortality rates for those aged 15 and older increased 62% between 1997 and 2002, while the rates for those aged 25–44 doubled in number.

Not all the news out of Africa is bleak. Zimbabwe is showing a decline of national HIV prevalence, apparently due to increased AIDS awareness and changes in sexual behavior. In East Africa, there is a trend of declining or stabilizing HIV prevalence. Uganda has had steadily declining adult HIV infection prevalence levels since peaking at > 15% in the early 1990s, to 6.7% in 2005. Kenya is the only other sub-Saharan country to have a declining HIV prevalence rate, from 10% in the late 1990s to 7% as of 2003, and 6% in 2005. More dramatically, the prevalence rates of HIV among attendees at urban antenatal clinics dropped from 28% in 1999 to 9% in 2003. These declines have been attributed to behavioral changes such as increased condom use with casual partners and decreased rates of multiple sexual partners, resulting from a national prevention campaign in 2000. However, the incidence of HIV infection peaked in the mid-1990s, suggesting that other factors such as the saturation of HIV infection in the population at risk may have influenced this decline.

In Asia, the prevalence data may mask the realities of the epidemic. Countries like India and China, each with a population over 1 billion, can have prevalence levels < 1%, yet still harbor millions of infected individuals. India, with 5.7 million infected patients in 2005, is one of the countries with the highest number of HIV-seropositive people in the world. India’s HIV epidemic closely mirrors Africa’s, being predominantly spread by heterosexual transmission. The control of HIV infection in Thailand is a qualified success. Their epidemic peaked in the mid-1990s, with HIV prevalence rates at prenatal clinics > 2.5% in some provinces. By 2004, it hovered around 1% for all provinces. The epidemic in Thailand was mainly heterosexual, being spread between commercial sex workers and their clients. Extensive education campaigns increased condom use to as high as 96%. Vigilance is required to maintain those levels, because recent surveys suggest condoms are now used only 50% of the time.

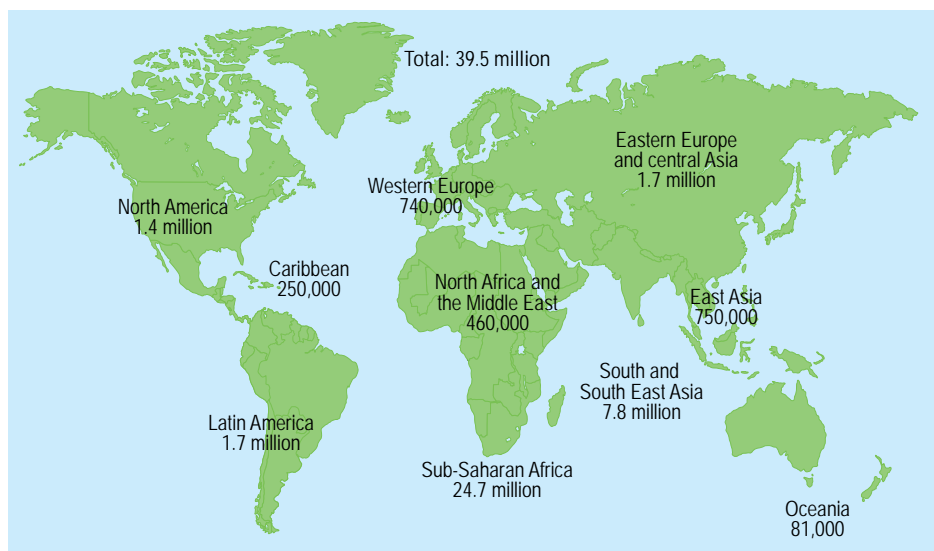

Fig. 37.1 Global prevalence of human immunodeficiency virus (HIV) infection: 39.5 million (modified from UNAIDS, December, 2006).

Russia has the largest HIV epidemic in Europe, with approximately 350 000 cases documented since the HIV epidemic began; however it is estimated that because of the poor reporting system, the actual number of people living with HIV is 940 000. The Russian epidemic has historically been one of IDUs, with greater than 80% of all reported HIV infections belonging to IDUs. However, in time IDUs infected from sharing needles engage in sexual relations, with the potential to spread the virus. In 2001 only 6% of registered cases were due to sexual transmission; by 2004 the number was 25%. Ukraine has an HIV prevalence of 1.5% (2005), the highest in Europe. Their epidemic, like Russia, began and continues to be fueled by IDUs. In a similar pattern, commercial sex workers are beginning to change the face of the epidemic. In 1999 only 14% of new infections were related to sexual transmission, but by 2004 that number was 32%, most of whose sexual partners were infected from contaminated needles.

Although the absolute number of HIV-positive cases is relatively small, the Caribbean is the second most affected area of the world behind Africa when considering national HIV prevalences. However, the region's prevalence of 1.6% is considerably less than sub-Saharan Africa's 7.2%. The epidemic is mostly related to heterosexual transmission, with male homosexual transmission being around 10%. Latin America had 1.8 million infected individuals in 2005, mostly as a result of sexual spread. In Argentina, the epidemic began among IDUs but, as in other Latin American countries, sexual transmission is now predominant, mainly affecting men who have sex with men (MSM).

According to the UNAIDS, in North America and western and central Europe there were an estimated 2.1 million people living with HIV, 43 000 new infections, and 18 000 deaths in 2005.

KEY CONCEPTS

TRENDS IN HUMAN IMMUNODEFICIENCY VIRUS (HIV) INFECTION

- >> Global rates of HIV infection continue to increase
- >> The increases are mostly in heterosexual transmission
- >> The age demographic most affected in the developing world, i.e., those aged 25–44 years, includes men and women who are economically productive and women of childbearing potential
- >> Six African nations have prevalence rates > 20%
- >> In the USA, African-American transmission in men who have sex with men is one of the key drivers of new infections

US PERSPECTIVE

The epidemic in the USA represents the changing face of the epidemic from one principally of transmission by Caucasian MSM and IDUs to a greater representation of minorities and women infected through heterosexual contact. The epidemiological data from the Centers for Disease Control and Prevention (CDC) suggest an adult and adolescent prevalence rate of 20.2/100 000 individuals, which translates into 476 095 people at the end of 2005.² The numbers of newly infected people in the USA decreased from 2001 to 2004, but in 2005 increased again by 1% (Fig. 37.2). The rates of new infection increased among those aged 15–29 and over 40. It decreased, however, in those aged < 13 and those aged 30–39. The incidence in those less than 13 has dropped 61% since 2000. New HIV cases increased among Caucasians, Asians, and American Indians, while decreasing by 10% in African-Americans and by 9% in Hispanics. African-Americans made up the majority of new

Fig. 37.2 US trends in human immunodeficiency virus (HIV) infection by sex and mode of transmission. IDU, intravenous drug users; MSM, men who have sex with men. (From Centers for Disease Control and Prevention: HIV/AIDS Surveillance Report, vol. 17, 2005, Atlanta: US Department of Health and Human Services, Centers for Disease Control and Prevention, 2006. Also available at <http://www.cdc.gov/hiv/topics/surveillance/resources/reports.gov>.)

infections, accounting for 50% of new cases. Males represented 73% of new cases, with 64% of those being among MSM, 16% from heterosexual transmission, and 13% from IDUs. In women, heterosexual contact accounted for 78% of new cases. In children < 13 years of age, 85% of the 166 cases were from perinatal transmission. There were 44 198 newly diagnosed AIDS cases in the USA in 2005, up from 38 016 in 2001. The number of deaths among patients with AIDS declined 8% from 2000 (44%) to 2004 (36%). Since the start of the epidemic in 2004, the total US deaths due to AIDS were estimated to be 529 113.

Among adolescents (13–19 years old), there were 1268 new cases of HIV in 2005, representing a 19% increase over 2001. The total number of adolescents living with HIV/AIDS in 2005 was 5322, a 46% increase over 2001 levels. These numbers are underestimated, as it is assumed that over one-third of HIV-infected adolescents in the USA have not been tested for HIV. Half of the 40 000 new cases of HIV infection in 2004 occurred in individuals under the age of 25.³

Fig. 37.3 Structure of human immunodeficiency virus (HIV) virion. (From Baliga CS, Shearer WT. HIV/AIDS. In: Fireman P (ed.) Atlas of allergy, 3rd edn. Philadelphia: Elsevier Science (USA), 2005:351–367, with permission from Elsevier.)

VIROLOGY

CLASSIFICATION

HIV is an enveloped, positive-sense RNA virus with icosahedral symmetry and two copies of its genome. It belongs to the lentivirinae group of retroviruses (Fig. 37.3). As with all retroviruses, it contains the enzyme reverse transcriptase (RT) capable of turning its RNA genome into DNA, which is integrated into the host cell genome and can then be translated to produce viral proteins and new virions. Like other lentiviruses such as equine infectious anemia virus, visna/maedi virus, and the other immunodeficiency viruses (bovine, feline, and simian), HIV has a long latency period before causing clinical disease.

There are two distinct types of HIV, HIV-1 and HIV-2. Both cause human immunodeficiency, but HIV-2 is mostly found in West Africa, is less pathogenic than HIV-1, and may have a longer latency period. Phylogenetic studies have found that HIV-2 is more closely related to SIV_{smm} (simian immunodeficiency virus (SIV) found in sooty mangabey monkeys) and SIV_{syk} (SIV found in Skyes' monkeys) than to HIV-1. HIV-1 is more closely related to SIV_{cpz} (SIV from chimpanzees). These associations support the presumed origin theories of HIV-1 evolving from infected chimpanzees and HIV-2 from sooty mangabeys (SMs). Based on the same genetic studies and estimated mutation rates, the transmission from *Pan troglodytes* chimpanzees to humans is thought to have occurred around 1930.

HIV-1 can be further subdivided based on the genetic divergence in the *env* gene.⁴ With divergences of 30–50%, HIV-1 has been divided into three groups: M (major or most), O (outlier), and N (new or non-M, non-O). The M group is further subdivided into clades (A–H, J, K, and O), each of which differs from each other by 20–30%. Clade B is most common in the industrialized world, including the USA. C is the most common clade worldwide, being present in Africa and South Asia. D is found mostly in central and East Africa. E, or rather the AE recombinant form, is the dominant strain in Southeast Asia. Clades A, D, G, H, K, and AG recombinants are found in Africa. F can be found in Africa, South America, and Eastern Europe. J can also be found in Central America.

STRUCTURAL GENES: *GAG*, *POL*, AND *ENV*

The HIV genome is 9.8 kb in length and can be divided into three groups of genes: structural, regulatory, and accessory (Fig. 37.4 and Table 37.1).

The 55-kDa Gag polypeptide (p55) is encoded by the HIV *gag* gene. After translation, the N-terminal is myristoylated, causing it to localize to

the cell membrane where it recruits two copies of viral RNA and other viral and cellular proteins, culminating in the budding and release of intact HIV particles. After budding, p55 is cleaved by the viral protease to give five proteins: capsid (CA, p24), matrix (MA, p17), nucleocapsid (NC, p9), p6, and p2. Gag cleavage is not required for viral particle formation, but it is necessary for the virus to be infectious. The matrix remains attached and stabilizes the viral envelope and with the capsid forms the conical core of the virus. The nucleocapsid is responsible for recognizing the “packaging signal” of the viral RNA and thus incorporating it into the developing viral particle. The p6 protein is used to recruit the HIV protein Vpr into the budding viral particle as well as being necessary for budding to occur. The last component, p2, is a spacer region between CA and NC, which is thought to be important in the stabilization of the CA core particle. Some authors consider p2 to be part of CA.

The *pol* gene encodes protease (PR, p10), integrase (IN, p50), RNase H (p15), and RT (p31). Pol is translated in a complex with Gag (Gag–Pol, p160) by a ribosomal frame-shifting event toward the distal end of *gag*. This occurs ~5% of the time, resulting in a ratio of p55:p160 of 20:1. PR cleaves the Gag–Pol complex into Gag and Pol. It further cleaves Pol into the above components. This cleavage is often incomplete, with 50% of RT remaining complexed to RNase H. Functional PR exists as a dimer and is an aspartyl protease. The IN protein has three functional activities: an exonuclease, endonuclease, and a ligase. It first removes the terminal two nucleotides from the linear double-stranded viral DNA through its exonuclease function. This results in the virus having “sticky ends.” Then it cleaves the host DNA at integration sites, allowing the sticky ends of the viral DNA to complement the ends of the host DNA through its endonuclease function. Finally, utilizing its ligase function, it covalently joins the viral DNA with the host’s. RNase H is capable of cleaving RNA if it is part of an RNA–DNA duplex. This is important

Fig. 37.4 Human immunodeficiency virus (HIV) genome: LTR, long terminal repeat; the products of *pol*: IN, integrase; PR, protease; RT, reverse transcriptase.

Table 37.1 Human immunodeficiency virus (HIV) proteins and their major functions

	Protein	Function
Structural proteins	Gag	Cleavage gives rise to capsid, matrix, nucleocapsid, and p6
	Pol	Cleavage gives rise to protease, integrase, RNase H, reverse transcriptase
	Env	gp120 and gp41
Regulatory proteins	Tat	Stabilizes transcription complex on the LTR and increases processivity of the complex
	Rev	Allows export of the viral RNA out of the nucleus
Accessory proteins	Nef	Downregulates MHC class I expression
	Vif	Ubiquitination and subsequent degradation of APOBEC3G
	Vpr	Arrests cell in G2/M phase of cell cycle
	Vpu/Vpx	Ubiquitinates CD4 in the endoplasmic reticulum

MHC, major histocompatibility complex.

in removing the RNA template from the negative-strand DNA and allowing the positive strand of DNA to be synthesized.

The protein Env, or gp160, is the product of *env*. After translation, Env is processed in the Golgi bodies such that it is glycosylated. A cellular protease cleaves gp160 into gp120 and gp41. The transmembrane domain of Env is gp41. This is also the fusion domain involved in HIV infection. Glycoprotein 120 acts as the ligand for HIV, binding to CD4 and the chemokine receptors CXCR4 and CCR5.

REGULATORY PROTEINS: TAT AND REV

The regulatory proteins Tat and Rev are essential for HIV replication. Tat stands for trans-activating factor.⁵ Without Tat the processivity is poor, although the HIV viral promoter LTR (long terminal repeat) is efficient in initiating DNA translation. This indicates that the transcription complexes easily bind on to the LTR and initiate viral RNA synthesis, but fall off the template before reaching the termination sequences. In fact, without Tat, only 10% of the RNA products are complete. Tat binds to the transactivation response element (TAR) and facilitates the binding of several accessory proteins to the transcription complex, notably the Tat-associated kinase (Tak) with cyclin T and

Cdk9 (Fig. 37.5). This complex increases the processivity of the transcription complex 100-fold. Numerous other actions have been linked to Tat, especially when it is added to cultures of cells different from lymphocytes, such as neuronal cells. These include activating the target cells, inducing production of Bcl-2, a protein that inhibits apoptosis. Tat has also been implicated in neurotoxicity and in endothelial, glomerular, and myocardial cell dysfunction, using *ex vivo* or animal model systems. However, it still remains controversial whether significant effects are exerted *in vivo* where the vast majority of Tat remains confined within the nucleus and nucleolus.

HIV encodes 11 proteins from a single RNA transcript, which is then multiply spliced. To perform this task, HIV's Rev binds to the Rev responsive element (RRE) in the *env* sequence as well as to a nuclear export signal known as CRM1, which directs the RNA to an accessory pathway in the nucleus. This pathway is permissive to the passage of RNA messages containing both introns and exons into the cytoplasm. Without Rev, only Tat and Nef would be synthesized by HIV.⁶

ACCESSORY PROTEINS: NEF, VIF, VPR, AND VPU/VPX

The accessory proteins, Nef, Vif, Vpr, and Vpu (or Vpx in HIV-2) are not required for viral replication, but they help the efficiency of this process. Nef stands for negative factor, a misnomer from early studies with lab-adapted strains of HIV where mutations in *nef* led to increased viral production. Nef has numerous effects (Fig. 37.6).⁷ It downregulates CD4 by promoting its endocytosis and lysosomal degradation. This helps the virus budding by removing the Env receptor from the cell surface. Nef also reduces the expression of major histocompatibility complex (MHC) class I on the cell's surface, thus limiting the ability of infected cells to be cleared by the immune system. It also activates T cells by binding to the T-cell receptor and several downstream effectors. Activated T cells translocate transcription factors NFAT and NF- κ B to the nucleus where they are thought to prime the viral promoter, leading to greater HIV transcription. Recent studies have found that Nef recruits the protein Eed out of the nucleus. Eed is found to colocalize with the HIV promoter and inhibit Tat transactivation. The addition of Nef causes Eed to shift rapidly to the plasma membrane and cease acting on the viral promoter.

Vif stands for virion infectivity factor.⁸ It is a 23-kDa polypeptide whose function remained unclear for many years. It was known that its

Fig. 37.5 Tat transactivation: human immunodeficiency virus (HIV) Tat forms a complex with various proteins, including cyclin T1 and Cdk9, which recognizes and binds to the TAR or transactivation response element in the nascent viral RNA. This complex then phosphorylates the carboxyl-terminal domain of RNA polymerase II (RNA Pol II), thus counteracting inhibitory factors that actively suppress transcription.

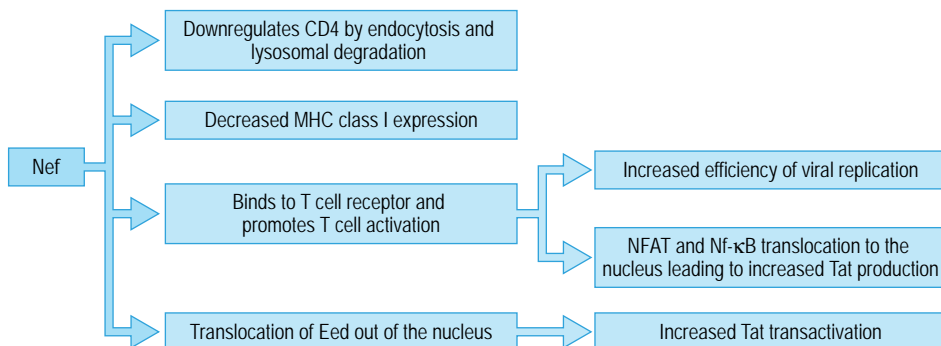

Fig. 37.6 The many functions of Nef. MHC, major histocompatibility complex.

Fig. 37.7 Vif and APOBEC3G: APOBEC3G acts on the first strand of synthesized viral DNA to deaminate cytosine, thus converting it to uracil. The uracil leads to the incorporation of an adenine into the complementary DNA strand instead of a guanine, thus affecting a C/G → T/A mutation on the viral genome. The presence of uracils in single-stranded DNA can directly lead to the degradation of that DNA strand. Vif and other proteins bind to APOBEC3G and ubiquitinate it, leading to proteasomal degradation. (From Harris RS, Liddament NT. Retroviral restriction by APOBEC proteins. *Nat Rev Immunol* 2004; 4: 868–877, with permission.)

presence allowed HIV strains to replicate in peripheral blood lymphocytes and certain 'restrictive' cell lines. Even without it, Vif-deficient HIV could replicate in the majority of cell lines commonly used in labs – so-called "permissive" cell lines. This suggested the presence of a cellular factor that was inhibiting HIV replication in certain cell lines that could be counteracted by Vif. A landmark paper in 2002 by Sheehy et al.,⁹ identified such a factor, APOBEC3G. This discovery also included the observation that retroviruses have genomes containing many adenines. This had also been observed in mutation studies of retroviruses in which a high frequency of guanine-to-adenine mutations was noticed, a phenomenon called retroviral hypermutation. APOBEC3G is a cytosine deaminase that mutates cytosines to uracils on the first strand of HIV DNA synthesized during viral replication (Fig. 37.7), resulting in the second strand containing an adenine instead of a guanine as the retroviral RT recognizes uracil as a thymidine. APOBEC3G is part of a family of APOBEC proteins (apolipoprotein B (APOB) mRNA-editing, catalytic polypeptide), which work by deaminating cytosine and inducing mutations, either to generate genetic diversity or inactivate viruses such as HIV or hepatitis B. Vif acts along with several other cellular cofactors like elongin B, elongin C, and cullin-5 (CUL5) to form an ubiquitin-ligase

complex, which leads to the polyubiquitination of APOBEC3G and to a proteosomal degradation pathway. Interestingly, simian APOBEC3G is not affected by HIV Vif and conversely the human APOBEC3G is not affected by SIV Vif. This may help to explain the species restriction of HIV and SIV. This viral specificity is dependent on one amino acid difference in the two APOBEC3Gs (defined below). Vif does not completely negate APOBEC3G's effect, as there is still a substantial amount of G-to-A mutations occurring in HIV.

The viral protein R (Vpr) has several functions assigned to it.¹⁰ It is best known for its ability to arrest the cell cycle in the G2/M phase through phosphorylation of Cdc2 and inhibition of the phosphatase Cdc25C, as well as for its part in helping the pre-integration complex navigate through the cytosol into the nucleus. It recognizes various nuclear localization signals and disrupts the nuclear membrane in nondividing cells. Vpr has recently been implicated in the induction of apoptosis. While low levels of expression seem to have an anti-apoptotic effect, higher levels promote apoptosis through caspase-dependent mechanisms.

Viral protein U (Vpu) is found in HIV-1 and SIV_{CPZ}.¹¹ Vpx is its analogue in HIV-2 and SIV_{MAC}. Vpu has two main functions in HIV pathogenesis. The high affinity of CD4 for Env suggests that both proteins can and do interact in the ER when they cross it together. Vpu binds to CD4 in the ER and leads to the ubiquitination of CD4 to allow free Env migration to the cell surface and into nascent HIV particles.

ORIGINS OF HIV

Phylogenetic analysis of HIV and SIV genomes has led to the hypothesis that HIV-1 originated in chimpanzees, specifically *Pan troglodytes*.¹² Recent painstaking work has identified chimpanzee communities in Cameroon that harbor endemic SIV_{cpz} infection, with prevalence rates of 29–35%. Two separate communities have been implicated as the origins of group M and group N HIV by phylogenetic analysis (Fig. 37.8).¹³ Chimpanzees and SMs become infected with their equivalent of HIV, SIV_{cpz} or SIV_{smm} respectively, but they do not develop simian AIDS (SAIDS). This failure to progress to SAIDS was initially thought to be the result of effective immune control of the virus; however, research has shown that, although these animals do mount cellular and humoral immune responses against the virus, they continue to have significant levels of replicating virus. Surveys of these animals show that they have an average viral load of 171 000 copies/mL and an average CD4 T-cell count of 1076 cells/mm³. Additionally, there is no correlation between viral load and CD4 T-cell count in chimpanzees, a striking difference from human studies where increased viral load correlates directly with decreased CD4 T-cell count.

Two subsets of SMs have been described, CD4-high and CD4-low. The CD4-high animals have normal CD4 T-cell counts and compose 85–90% of studied SMs. The CD4-low animals show evidence of typical CD4 T-cell depletion, but without evidence of SAIDS. Whether these CD4-low animals represent an intermediate between the majority of animals that do not develop SAIDS and those that become sick is unclear. Only one SM has ever been documented to have SAIDS. Levels of CD4 and CD8 T-cell activation also demonstrate limited activation in SMs as defined by interferon-γ (IFN-γ) or tumor necrosis factor-α (TNF-α) secretion following exposure to pooled SIV peptides. Only 0.45% and 0.26% of CD8 and CD4 T cells were reactive, respectively.¹⁴

Fig. 37.8 Phylogenetic trees of the full-length human immunodeficiency virus (HIV)/SIV_{cpz} genomes showing the evolutionary relationships between various chimpanzee populations and the crossover events of simian immunodeficiency virus (SIV) into the human population to give HIV groups M, N, and O. The numbers on the branches represent the posterior probability, and the arrows indicate the crossover events. (From Keele BF, Van Heuverswyn F, Li Y, et al. Chimpanzee reservoir of pandemic and nonpandemic HIV. *Science* 2006; 313: 523–526, with permission from AAAS.)

This again differs from human responses to HIV where 0.7% and 6.3% of CD4 and CD8 T cells, respectively, react to pooled peptides.¹⁵

ROUTES OF INFECTION

HIV is transmitted through three routes of infection: sexual, parenteral, and perinatal (Table 37.2). In general, higher viral loads, lower CD4 T-cell count, and viral inoculum size are all associated with a greater risk of transmission.

Sexual transmission, representing 70–80% of worldwide infections, is the most common mode of infection. Besides the factors mentioned

above, recipients of penetrative intercourse are more likely to become infected. Anal intercourse carries the greatest risk, followed by vaginal intercourse, with oral intercourse the least likely to spread the virus. The presence of other sexually transmitted diseases, especially ulcerative lesions such as those seen in herpes simplex or syphilis infection, increases the risk of transmission. In contrast, male circumcision significantly decreases transmission risk.¹⁶

Parenteral transmission is the second most common route of HIV infection, accounting for 8–15% of all HIV infections. Examples include contaminated needles among IDUs, accidental needlesticks among health care workers, improperly sterilized hospital equipment, and contaminated blood products. The largest component of this category is contaminated

KEY CONCEPTS

HUMAN IMMUNODEFICIENCY VIRUS (HIV) AS A ZOONOSIS

- >> The natural reservoir of HIV prior to widespread human infection seems to have been chimpanzees for HIV-1, and sooty mangabeys for HIV-2
- >> Each of the three groups of HIV-1 – M, N, O – is thought to represent separate transmission events from chimpanzees to humans
- >> The natural hosts of the simian immunodeficiency virus (SIV) have a less robust immune response than humans, have poorer viral control, but only rarely show CD4 T-cell loss or progress to immunodeficiency
- >> The ability of SIV to replicate in some nonhuman primates without causing overt disease may hold important knowledge needed for the management of the pandemic in humans

Table 37.2 Routes of human immunodeficiency virus (HIV) infection

Mode of transmission worldwide	Percentage of cases
Sexual	70–80
Vaginal intercourse	60–70
Anal intercourse	5–10
Perinatal	5–10
<i>In utero</i> and intrapartum	2.5–5.0
Postpartum	2.5–5.0
Parenteral	8–15
Injecting drug abuse	5–10
Blood transfusions	3–5

From Baliga CS, Shearer WT. HIV/AIDS. In: Fireman P (ed.) Atlas of allergy, 3rd edn. Philadelphia: Elsevier Science (USA), 2005:351–367, with permission from Elsevier.

needles by IDUs. Russia, Eastern Europe, and northeastern India all have HIV epidemics dominated by parenteral spread through contaminated needles. Epidemics of iatrogenic infections have occurred in Russia, China, and other developing countries as a result of improperly sterilized medical equipment or improper screening of blood products. Even in developed countries, prior to effective screening for HIV in 1985, many individuals were infected with blood product transfusions.

Perinatal transmission accounts for the majority of pediatric HIV cases and for 8–15% of HIV infections in all-aged patients. The virus is capable of infecting the child *in utero*, during labor, and after delivery through breastfeeding. The risk of a child contracting HIV from his or

her mother during gestation or during labor is ~25%. It is thought that the majority of transmission events occur during the passage of the fetus through the birth canal, by the baby swallowing infected maternal blood, amniotic fluid, and/or cervical and vaginal secretions. An increased rate of abortions and female subfertility has been reported in HIV-infected women. This suggests an unfavorable effect of HIV on early gestation, likely reflecting transplacental passage of the virus. Breastfeeding confers an additional 15–29% increased risk of transmission of the virus from mother to child. Factors such as cracked or ulcerated nipples, mastitis, duration of breastfeeding, and prematurity of the infant may increase the risk of infection.

Recent studies suggest a role of the maternal innate immune system in modulating *in utero* and intrapartum transmission risks. Certain human leukocyte antigen (HLA)-B alleles in the mother encoding killer cell-immunoglobulin-like receptor (KIR) ligands decreases the risk of maternal transmission, suggesting that the involvement of natural killer (NK) cells in the mother is an important determinant of the risk of HIV transmission to the fetus.¹⁷

IMMUNOPATHOGENESIS

Following a mucosal inoculation of HIV, CD4 T cells are initially infected by CCR5-tropic virus, also called R5 or M-tropic virus. In the macaque model, it takes 3 days for HIV-infected cells to be identified. After a week, the virus becomes detectable in draining regional lymph nodes. Myeloid dendritic cells are not infected with HIV; rather HIV gp120 binds to dendritic cell-specific intercellular adhesion molecule-grabbing nonintegrin (DC-SIGN). The resulting complex is internalized as a phagosome and then presented on the cell surface. As there is no fusion of the HIV Env with the cell membrane, infection does not occur. It has been suggested that the acidic environment of the phagosome potentiates the infectivity of HIV. Plasmacytoid dendritic cells, on the other hand, express CD4 and the co-receptors CXCR4 and CCR5 and thus become infected by the virus. Infection leads to expression of CCR7, which acts as a homing signal for the lymph nodes; it is in lymph nodes where the virus infects T cells, and viral replication occurs. It is at this time that detectable viremia first occurs and the virus begins to seed lymphoid tissues.

GASTROINTESTINAL SYSTEM: EARLY TARGET

A recent advance in the understanding of HIV pathogenesis comes from the evidence of massive infection and subsequent destruction of memory T cells in the gut-associated lymphoid tissue (GALT).¹⁸ Within days, 20% of the GALT CD4 T cells are infected and, of these, up to 80% are killed, likely by direct virus-mediated cytotoxicity or Fas-mediated apoptosis. By the time of peak viremia, 60% of the mucosal memory CD4 T cells are infected. It should be noted that the majority of the body's CD4 T cells reside in the GALT and that this massive infection and destruction of these cells occur early in the infection. Circulating CD4 T cells counts do not reflect the magnitude of CD4 T-cell death taking place in the GALT. The initial surge in viral load and its subsequent lowering to a setpoint is often attributed to the time it takes for the body's adaptive immune system to control the virus. To some extent this is true as levels of specific cellular and humoral immunity correlate with viremic control. However, given the new knowledge of the events transpiring in the GALT, one could argue that the initial

rise in viral load represents the rampant proliferation and infection of cells in the GALT, and the subsequent lowering to the viral setpoint represents the depletion of most of the body's CD4 T cells. In other words, if there were fewer cells to support viral replication, levels of viremia would decline.

Following HIV infection, a massive activation of the immune system occurs. Soluble HIV proteins have long been implicated as the cause of this activation, and *in vitro* data support this theory. Lack of a memory response could lead to infection and inflammation of the entire bowel, or possibly the high level of proinflammatory cytokines released by the destruction of the memory CD4 T-cell compartment could lead to increased permeability of the mucosa and translocation of immunogenic peptides from the lumen into the tissue. In either case, the presence of these immune activators over the massive surface area of the bowel has been hypothesized to result in the profound immune activation seen in HIV.¹⁹

Without treatment, the viremia decreases from as high as 10 million copies of HIV RNA/ml during the acute illness to a stable level called the viral setpoint. The determinants of the setpoint remain unclear. It is known that higher setpoints, which indicate higher viral loads, are loosely predictive of shorter periods of clinical latency. On average, this plateau, or more accurately this period of gradual decline in CD4 T-cell counts and gradual rise in viral load, lasts for 7–10 years. During this time, massive immune activation persists with rapid turnover of cells and with lymph nodes becoming fibrotic. Eventually, for unclear reasons, the relative period of homeostasis between the virus and the immune system collapses and AIDS ensues.

CELLULAR IMMUNITY

The thought that cellular immunity, or specifically CD8 T cells, is important in controlling HIV is supported by several observations. Studies in macaques have shown that when CD8 T cells have been depleted, animals have experienced increased viral loads and rapid clinical progression toward SAIDS.²⁰ In SIV- or HIV-infected individuals, the initial control of viremia occurs with the initial expansion of HIV-specific CD8 T cells.^{21,22} HIV-exposed but uninfected individuals possess HIV-specific CD8 T-cell responses. The importance of anti-HIV cytotoxic T cells is suggested by the development of viral escape mutations.^{23,24}

HIV-infected individuals present with HIV-specific CD4 T cells, which secrete IFN- γ , even though HIV-specific CD4 T cells are severely reduced in number.²⁵ In other words, there is not so much a lack of CD4 T-cell response as there is a change in the quality of the response, at least early in the infection. Studies of the correlates of immunity against other chronic viral diseases like Epstein-Barr virus and cytomegalovirus (CMV) demonstrate three qualitatively different CD4 T-cell antiviral responses: (1) an IFN- γ predominant response associated with high viremia and poor immune control; (2) an IFN- γ and interleukin-2 (IL-2) response associated with low-level viremia; and (3) an IL-2 predominant response associated with clearance of viremia. Interestingly, HIV-infected patients with long-term nonprogressor disease course (LTNPs) had identifiable IL-2 and IFN- γ -secreting HIV-specific CD4 T cells. Similarly, HIV-specific CD8 T cells tend to secrete mostly IFN- γ , rather than the broader phenotype in Epstein-Barr virus and CMV infection where CD8 T cells are able to proliferate and secrete IL-2.

HUMORAL IMMUNITY

After establishment of HIV infection, neutralizing antibodies begin to be found in the circulation of patients. These antibodies are effective in neutralizing the virus; however, the virus quickly mutates to avoid them, such that the host is always chasing after the virus. The fact that antibodies can be effective in protecting hosts from HIV infection has been demonstrated in macaques and in a mouse model. Passive transfer of neutralizing antibodies to macaques was sufficient to protect them from a homologous virus challenge.²⁶ Similarly, in immunodeficient mice transplanted with human T cells, passive transfer of neutralizing antibodies protects against homologous HIV infection.²⁷ More recent studies have demonstrated protection in macaques when topical neutralizing antibodies were applied prior to challenge with homologous virus.²⁸ Antibodies directed against Env encounter gp120 and gp41 complexed with each other as heterodimers and homotrimers. This particular conformation has the effect that much of the surface area of Env is unavailable to the host immune system. In addition, the exposed surface of gp120 is heavily glycosylated, the so-called glycan shield. The carbohydrate moieties are provided by the host cellular machinery, and therefore are poorly immunogenic. Their locations within the gp120 molecule are driven by immune pressure. Furthermore, the external V1 and V2 loops of gp120 sterically guard the CD4 binding site, whereas the V3 loop guards the co-receptor binding site. All of the loops can vary considerably in response to host immune pressure without apparent penalty to the virus. The co-receptor binding site on gp120 is not exposed until it undergoes a conformational change caused by binding to CD4, thus limiting the time it is exposed to potential antibodies.

While many neutralizing monoclonal antibodies have been identified and studied, only five are broadly neutralizing for many different viral strains. Monoclonal antibody b12 recognizes the CD4 binding site on gp120, whereas monoclonal antibody X5 binds to the co-receptor binding site when it is exposed. Probably due to steric limitations, it is only effective as an Fab fragment. Monoclonal antibody 2G12, another neutralizing antibody, binds to mannose residues on the surface of gp120. The remaining two, monoclonal antibodies 2F5 and 4E10, bind to the membrane proximal region of gp41.

INNATE IMMUNITY

NK cells

The phenotype of NK cells is dramatically altered in HIV infection.²⁹ This is hypothesized to occur due to three possible mechanisms: (1) direct infection of NK cells by HIV; (2) binding of NK cell chemokine receptors by HIV; and (3) other effects of the generalized immune activation found in HIV infection. A small subset of NK cells has been found to express both CD4 and CCR5 or CXCR4. These NK cells can be infected by HIV and may serve as one of the sites of latent infection. NK cells also express chemokine receptors that can be triggered by HIV, thus altering their phenotype through downstream signaling. CCR5 levels are higher on NK cells in HIV-infected patients than in HIV-seronegative subjects. However, the increased expression of CCR5 may represent an effect of generalized immune activation rather than an HIV-specific effect. Interestingly, the expression of inhibitory NK cell receptors (for example CD94, CD85) is also increased in HIV infection,

Table 37.3 Apoptosis by human immunodeficiency virus (HIV) products: extrinsic pathway

HIV product		Mechanism of extrinsic pathway apoptosis	
gp120	Increase CD95 and CD95L	Increase caspase-8	Increase activity of caspase-3

Tat	Increase CD95 and CD95L	Increase TNF-related apoptosis-inducing ligand (TRAIL)	Increase caspase-8
Protease			Increase caspase-8

TNF, tumor necrosis factor.

but returns to normal following highly active antiretroviral therapy (HAART). Surface expression of NK cell protein 30 (NKp30), NKp44, and NKp46, receptors on NK cells that induce cytotoxic activity, is reduced in HIV infection. Antibody-dependent cell-mediated cytotoxicity (ADCC) is reduced in HIV-infected patients, as well as the NK cell responsiveness to IL-2.

NK cells detect the lower levels of MHC class I molecules on HIV-infected cell surfaces, and through ADCC or direct cytotoxic effects are able to induce death of cells infected with HIV *in vitro*. However *in vivo* studies have failed to demonstrate this effect. This is thought to be secondary to the preservation of HLA-C and -E molecules. The expression of HLA-C-specific inhibitory NK cell receptors has been found to be increased in HIV patients. Another way NK cells can inhibit HIV infection is through the production of chemokines (CCL-3, 4, and 5), which competitively inhibit HIV binding to CXCR4 or CCR5. Interestingly, studies of Vietnamese seronegative but HIV-exposed IDUs showed that their NK cells not only secreted greater quantities of chemokines than controls, but they also had greater direct cytotoxicity.

Dendritic cells: myeloid and plasmacytoid

The two subsets of dendritic cells play an important role in HIV infection, serving as antigen-presenting cells, which can prime T cells via myeloid dendritic cells, as well as stimulating innate immune responses such as the type I interferons against HIV via plasmacytoid dendritic cells. In fact, low levels of plasmacytoid dendritic cells correlate with high viral loads, low CD4 T-cell counts, opportunistic infections, and disease progression. High levels of dendritic cells are found in LTNPs. HIV infection appears to activate plasmacytoid dendritic cells by stimulation of Toll-like receptor-7.

VIRAL EFFECTS ON THE HOST

Immune activation

HIV infection induces a profound proliferation and turnover of CD4 and CD8 T cells, even though only a minority of those cells are infected with HIV. It has been thought that HIV itself, either through

direct infection or through its protein products like Nef, Env, Vif, etc., induces this activation. This rampant immune activation has long been regarded as the impetus to the eventual collapse of the immune system, secondary to immune exhaustion, implying that the immune system can no longer maintain the high levels of circulating immune cells, T cells, B cells, and NK cells. Newer studies link the cause of the immune activation to an increased permeability of the gastrointestinal mucosa secondary to the heavy burden of HIV infection of mucosal immune cells.

Apoptosis

Increased apoptosis of T cells in HIV infection was established early in the epidemic. Several explanations have been offered: (1) HIV-induced apoptosis of infected cells (viral cytopathic effect); (2) a bystander effect from HIV-infected neighbor cells releasing viral proteins; (3) death of HIV-specific effectors following their migration to infected sites; (4) perturbation of pro-apoptotic signaling molecules on immune cells secondary to the chronic immune activation; and 5) destruction of HIV-infected cells by immune effectors.³⁰ Late HIV infection is associated with the dominance of a syncytia-inducing form of the virus. This virus induces syncytia formation (clustering of CD4 T cells and membrane fusion) through the interaction of Env and CD4/CXCR4 on neighboring cells. These cells are more prone to undergo apoptosis through a CD95-dependent pathway, likely potentiated by Vpu.

Most of the HIV proteins have been implicated at one time or another in HIV-induced apoptosis. Table 37.3 summarizes the proteins affecting the extrinsic pathway and Table 37.4 lists those affecting the intrinsic pathway.

Autophagy

Autophagy is a process by which cytoplasm and organelles are sequestered and directed toward lysosomal pathways. This process has been implicated in both preventing and inducing apoptosis, reflecting common regulating factors shared by both, e.g., TNF-related apoptosis-inducing ligand (TRAIL), FADD, DAPk, ceramide, and Bcl-2.³¹ Recently, HIV Env has been proposed as a stimulus for autophagy in uninfected CD4 T cells via its interaction with CXCR4.³² Inhibition of

Table 37.4 Apoptosis by human immunodeficiency virus (HIV) products: intrinsic pathway

HIV product		Mechanism of intrinsic pathway apoptosis	
gp120	Phosphorylation of p53	BAX insertion into mitochondrial membrane	Decreases BCL-2
Tat		BAX insertion into mitochondrial membrane	Decreases BCL-2
Vpr		Directly increases mitochondrial permeability	
Nef			Decreases BCL-2 Decreases BCL-XL
Protease			Cleaves BCL-2

the autophagic pathway prevented Env-induced cell death in uninfected cells *in vitro* and demonstrates that this mechanism contributes to the loss of uninfected cells.

The effects of increased apoptosis on the immune system are obvious. The abnormal levels of apoptosis might contribute to the paucity of CD4 T cells late in the disease course. Infected cells can die by the mechanisms mentioned above. Proliferating HIV-specific T cells are also more susceptible to HIV infection and subsequent cytopathicity, depriving the host of the very cells necessary to control viremia. Noninfected cells can be killed by the above mechanisms as well.

CYTOKINES

The dysregulation of the immune system produced by HIV infection includes significant perturbation in the balance of T-cell helper 1 (Th1) and Th2 cytokine levels, which can be observed by examining infected cells *in vitro* and by measuring plasma cytokine levels in HIV-infected patients. The Th1 cytokines IL-2, TNF- α , IFN- γ , and IL-12 decrease during HIV infection, while the Th2 cytokines, IL-10 and IL-4, increase or remain normal. In addition, levels of proinflammatory cytokines such as IL-1, IL-6, and IL-8 also increase.³³ These changes are dynamic, affected by responses to infections and the deterioration of immunity. They reflect the increased state of immune activation with destruction of T cells that are known to direct antiviral responses (Th1). The increase of IL-4 correlates with the hypergammaglobulinemia observed during the early stages of HIV infection.

Viral replication in HIV-infected T cells and monocytes is induced by IL-2, IL-7, and IL-15, as well as the proinflammatory cytokines. These cytokines appear to produce this effect by activating the host cell, a requirement for HIV productive replication.³⁴ Some cytokines, such as IL-10, decrease HIV production, likely by inhibiting the synthesis of the activating cytokines, and by decreasing the expression of CCR5 and other chemokine receptors.³⁵ In addition, the HIV LTR promoter contains sequences that bind cellular factors that are activated as a response to cytokine binding, such as NF- κ B and AP1. IFN- α and IFN- β have activity against HIV, although their role *in vivo* is not known. Some chemokines inhibit HIV infection by competing with their binding site.

The alpha-chemokine SDF-1 competes with the lymphotropic HIV strains for the binding of CXCR4, while the beta-chemokines MIP1 α , MIP1 β , and RANTES compete to bind CCR5 with the HIV macrophage-tropic strains. IL-2 and IL-7 have been tested as therapeutic adjuvants to antiretroviral therapy, in an effort to eliminate the viral reservoirs using their capacity to induce HIV replication out of latency.³⁶ Significant side effects and limited efficacy have decreased the enthusiasm for these strategies. The interaction of chemokines and their receptors is being investigated as a potential target for anti-HIV therapeutics.

CLINICAL FEATURES

ACUTE HIV INFECTION

The natural history of HIV involves four phases: acute retroviral syndrome, asymptomatic phase, pre-AIDS syndrome, and AIDS. There is an initial surge in viremia and loss of circulating CD4 T cells. As immune responses appear, the viremia declines to its setpoint and the CD4 T-cell counts rebound and stabilize. This balance between CD4 T-cell production and loss lasts for 7–10 years in most patients, following which the rates of CD4 T cells again begin their inexorable decline. With declining CD4 T cells, viral loads rebound (Fig. 37.9).

Acute retroviral syndrome occurs within a period of days to 6 weeks following infection with HIV. Viral loads of 10 million HIV RNA copies per ml of plasma are not uncommon. We now know that this initial burst of viremia likely represents the massive infection and subsequent destruction of the CD4 T-cell memory cells in the intestinal mucosa. Reflecting this, there is a rapid drop in circulating CD4 and CD8 T cells during the acute infection. CD8 T-cell numbers rebound, as do the CD4 T cells, albeit to a lesser extent. The symptoms of this initial illness are often described as being infectious mononucleosis-like (Table 37.5). Between 30% and 90% of patients present to the health care system at this point; however, given the nonspecific and “viral syndrome-like” nature of these complaints, they are rarely diagnosed. As the host develops cellular and humoral immunity against the virus, the viremia subsides and the symptoms abate.

Fig. 37.9 Natural course of human immunodeficiency virus (HIV) infection: the relationship between CD4 T-cell counts and viral loads over the course of infection in the absence of treatment. PCR, polymerase chain reaction. (From Baliga CS, Shearer WT. HIV/AIDS. In: Fireman P (ed.) Atlas of allergy, 3rd edn. Philadelphia: Elsevier Science (USA), 2005:351–367, with permission from Elsevier.)

Table 37.5 Clinical features of acute human immunodeficiency virus (HIV) infection

Symptoms

Fever
Fatigue
Weight loss
Rash
Headache
Sore throat
Myalgia
Fleeting arthralgia
Nausea/vomiting
Diarrhea

Signs

Tender lymphadenopathy
Pharyngitis
Meningismus
Mucocutaneous ulcerations
Morbilliform or maculopapular nonpruritic rash

Laboratory investigations:

Thrombocytopenia
Leukopenia
Elevated liver enzymes
Positive HIV RNA or DNA by polymerase chain reaction
p24 antigen
Positive viral culture

CLINICAL PEARLS

ACUTE INFECTION AS AN OPPORTUNITY FOR EARLY HUMAN IMMUNODEFICIENCY VIRUS (HIV) DIAGNOSIS

- >> Acute HIV infection is a nonspecific viral syndrome, often called infectious mononucleosis-like
- >> Many patients present to a clinician at this stage, but most are not recognized as HIV infection
- >> Animal studies suggest that irreparable damage to the host immune system occurs during this stage of HIV infection
- >> Those same models suggest that highly active antiretroviral treatment (HAART) initiated at this time can halt the destruction of the body's memory T cells in the gut-associated lymphoid tissue and lead to better long-term outcomes for the patient
- >> Some HIV clinicians downplay the practical importance of early therapy of acute infection as patients who are able to achieve and maintain undetectable viral loads on HAART do well, in spite of having commenced treatment long after their acute infection

A minority of patients develop a more fulminant course of disease and rapidly progress to AIDS. Most patients recover and remain clinically asymptomatic for a variable period of time, usually 7–10 years. In antenatal infection, there is a larger proportion of patients who rapidly progress to AIDS than in adult infection.

ASYMPTOMATIC HIV INFECTION

During this asymptomatic stage, HIV viremia decreases from the time of the initial infection to a level called the setpoint. This is thought to represent the balance between the virus' ability to replicate and destroy CD4 T cells and the host immune response's ability to suppress the virus. The setpoint has been thought to be one of the best predictors of disease progression. Patients with a high setpoint are more likely to progress to symptomatic disease in a shorter period of time than those with a low setpoint. A recent study, however, demonstrated that the setpoint, although loosely correlated with the rate of CD4 T-cell loss, does not adequately account for the rate of decline.³⁷ What determines a high viral setpoint versus a low one remains unclear. Presumably, those patients with a higher setpoint are infected with a more fit virus and/or have a less robust immune response than those with lower setpoints. LTNPs have been noted to have very low setpoints. Animal studies show that therapeutic vaccines, although unable to prevent infection, can reduce the viral setpoint and thereby prolong the period of clinical latency. While commonly thought to represent a plateau in the levels of viremia and CD4 T-cell counts, the period of clinical latency actually represents a prolonged, and in most people inexorable, decline of roughly 50 CD4 T cells a year. There is usually an 'inflection point' in the curve marking the start of a period of more rapid decline in CD4 T-cell counts. As these counts fall, immunodeficiency, symptomatic disease, and AIDS eventually occur.

SYMPTOMATIC HIV INFECTION (PRE-AIDS SYNDROME)

The pre-AIDS syndrome or symptomatic disease develops as the infection progresses. It consists of generalized lymphadenopathy, fever, night sweats, fatigue, diarrhea, weight loss, mucocutaneous fungal infections, aphthous ulcers, recurrent herpes simplex, molluscum contagiosum, condyloma acuminata, psoriasis, drug-induced skin eruptions, and seborrheic dermatitis. Patients may develop recurrent bacterial infections and tuberculosis. Thrombocytopenia, bacillary angiomatosis, cervical dysplasia, carcinoma-*in-situ*, oral hairy leukoplakia, recurrent and/or polydermatomal herpes zoster, listeriosis, pelvic inflammatory disease in women and peripheral neuropathy are evident as the disease continues to progress. In children, symptomatic HIV disease presentation occurs with anemia, neutropenia, or thrombocytopenia (lasting > 1 month), bacterial meningitis, pneumonia, oropharyngeal candidiasis (for > 2 months in children older than 6 months of age), cardiomyopathy, CMV infection (with onset less than 1 month of age), recurrent or chronic diarrhea, hepatitis, recurrent herpes simplex stomatitis, herpes simplex bronchitis, pneumonitis, esophagitis (with onset before 1 month of age), leiomyosarcoma, lymphoid interstitial pneumonia/pulmonary lymphoid hyperplasia complex, nocardiosis, or toxoplasmosis (with onset before 1 month of age).

END-STAGE HIV INFECTION: AIDS

As the CD4 T-cell count drops below 200 cells/ μ L, the immune system's ability to fight infection is sufficiently compromised so that AIDS-defining illnesses appear (Table 37.6). Certain infections are more common depending on how low the CD4 T-cell count goes. With a CD4 T-cell count < 200 cells/ μ L, *Pneumocystis jiroveci* pneumonia and coccidioidomycosis become more common. As this count drops below 100 cells/ μ L, *Toxoplasma* sp. and *Histoplasma* sp. emerge as common pathogens. Infections with *Mycobacterium avium* complex, *Cryptococcus* sp., and CMV become concerns at counts less than 50 cells/mm³. Prophylaxis for opportunistic infections is administered depending on the patient's CD4 T-cell counts (Table 37.7). Without treatment, most patients will not survive more than 2 years after developing AIDS, succumbing to any of the above opportunistic infections.

LONG-TERM NONPROGRESSORS

Some HIV-infected patients are called LTNP. These are patients who are infected with the virus but do not progress to AIDS after a defined period of time. Multiple studies use different definitions of the term, such that a consensus definition does not exist. The best definitions include time, CD4 T-cell levels, and viral load. One of the explanations to emerge was a deletion of 32 nucleotides in their *CCR5* gene (*CCR5-Δ32*). This deletion, thought to originate from selective pressure exerted by the bubonic plague, is found in people of European Caucasian ancestry. The deletion renders the CCR5 receptor nonfunctional, and as an essential consistency receptor for HIV entry, offers protection against viral infection. Other mutations have been identified, like the *CCR2-64I* gene mutation, the *SDF1-3'A* gene mutation, and the *RANTES-28G* gene mutation. However, these mutations are found only in a minority of LTNPs. APOBEC3G mRNA levels have been found to be elevated in LTNPs compared to noninfected controls and

Table 37.6 Acquired immunodeficiency syndrome (AIDS)-defining illnesses

Candidiasis of the trachea, esophagus, bronchi, trachea, or lungs
Invasive cervical cancer
Disseminated or extrapulmonary coccidioidomycosis
Extrapulmonary <i>Cryptococcus</i> infection
Chronic intestinal cryptosporidiosis
Cytomegalovirus infection of any organ other than the spleen, liver, or lymph nodes
Cytomegalovirus retinitis with loss of vision
Human immunodeficiency virus (HIV)-related encephalopathy
Herpes simplex: chronic ulcers or bronchitis, pneumonitis, or esophagitis
Disseminated or extrapulmonary histoplasmosis
Chronic intestinal isosporiasis
Kaposi's sarcoma

Progressive multifocal leukoencephalopathy
Recurrent <i>Salmonella</i> septicemia
Toxoplasmosis of the brain
Wasting syndrome

HIV-infected patients. An explanation for the APOBEC3G findings and for LTNPs is that they are infected with a defective or less fit virus. Alterations in the virus, presumably induced by the selective pressure of the immune system, antiretrovirals, or even the intrinsic poor fidelity of HIV RT, can create viral strains that are infectious but are somewhat hobbled by their mutations and therefore less pathogenic. Such molecular alterations have been described in Nef, Vif, and Vpr. Other more conventional mechanisms have been proposed, such as strong and broad neutralizing antibody and/or cytotoxic T-cell responses. HLA-B27 and -B57 have also been correlated with LTNPs. Prior studies had found that high levels of p24-specific IL-2 and IFN- γ production correlated with LTNPs, but subsequent studies failed to sustain this theory. CD4 Th1 responses specific to HIV p24 have been found to be predictive of LTNP in adults.³⁸ In children, CD8+ HLA-DR+ T-cell percentages < 5% at 1–2 months of age have been implicated in predicting LTNPs.³⁹ A recent study found circulating autoantibodies to a conformational epitope in the extra membrane loop of CCR5 that induce downregulation of the co-receptor in a subset of LTNPs. Interestingly, if the levels of those antibodies waned, the LTNPs were more likely to progress to symptomatic disease.⁴⁰ Table 37.8 summarizes factors that can affect HIV progression.

Table 37.7 Opportunistic infection prophylaxis and treatment in adolescents and adults^a

Risk factor	Agent	Prophylactic medication
CD4 cell count < 200 cells/μl	<i>Pneumocystis jiroveci</i>	Trimethoprim-sulfamethoxazole (TMP-SMX) or dapsone plus or minus pyrimethamine and leucovorin or aerosolized pentamidine or atovaquone
	Coccidioidomycosis	In endemic areas: fluconazole or itraconazole
CD4 T-cell count < 100 cells/μl	<i>Toxoplasma gondii</i>	TMP-SMX or dapsone plus pyrimethamine plus leucovorin or atovaquone plus pyrimethamine plus leucovorin
	Histoplasmosis	In endemic areas: itraconazole
CD4 T cell count < 50 cells/μl	<i>Mycobacterium avium complex (MAC)</i>	Macrolide (clarithromycin or azithromycin) or rifabutin
	Cryptococcosis	In endemic areas: fluconazole or itraconazole
PPD > 5 mm induration or recent TB contact but no active TB and no history of treatment for active or latent TB	<i>Mycobacterium tuberculosis</i>	INH + pyridoxine for 9 months; if unlikely to complete 9-month course and on HAART: rifabutin plus pyrazinamide for 2 months
Contact with chickenpox or shingles in varicella-zoster seronegative individuals	Varicella-zoster	Varicella-zoster immunoglobulins (VZIG)
HIV-infected	<i>Streptococcus pneumoniae</i>	Pneumovax
	Meningococcus – for youth attending the military or college and consider for unvaccinated adults	Menactra
Negative anti-HBc and previously unimmunized or underimmunized to hepatitis B	Hepatitis B	Recombivax-HB or Engerix-B
Negative anti-hepatitis A serology	Hepatitis A	Havrix

^aFor additional information see the current US guidelines at <http://AIDSinfo.nih.gov>.
HAART, highly active antiretroviral therapy; INH, ; PPD, purified protein derivative; TB, tuberculosis.

NONSUSCEPTIBILITY TO HIV INFECTION

Anti-CCR5 antibodies have been found in an interesting cohort of patients – those who have been repeatedly exposed to HIV but have not developed a detectable infection (i.e., HIV-exposed but seronegative patients). Many investigators have looked into this group of individuals, but have not found a good explanation for their lack of susceptibility to HIV infection. Very low levels of virus have been found in these seronegative patients, indicating that they have in fact been exposed. Other studies have implicated: (1) higher IFN- γ production by CD56⁺(bright) NK cells and CD3⁺/CD56⁺ cells; (2) low levels of baseline immune activation and immune responsiveness in T cell; (3) increased levels of immune responsiveness; (4) increased HIV-specific CD4 and CD8 T cells; (5) increased CD91 (low-density lipoprotein-related protein receptor) expression on monocytes; (6) mucosal CCR5-specific immunoglobulin A (IgA); and (7) mucosal HIV-

neutralizing antibodies. The question is whether these immune responses are the protective factor, or rather do they result from the act of exposure, leaving an as-of-yet-undefined factor as the explanation. Because no clear or obvious correlates of immunity have been found, the immune responses that have been measured are likely reactive and not causal.

■ DIAGNOSIS AND MONITORING OF PATIENTS ■

DIAGNOSTIC TESTS

The diagnosis of HIV is conventionally a two-step process. First, a screening enzyme-linked immunoabsorbent assay (ELISA) is performed, which has a high sensitivity but low specificity. If that test is

Table 37.8 Factors affecting human immunodeficiency virus (HIV) disease progression

Inoculum size	The higher the inoculum, the faster the disease progression
Primate species	Primates infected with their native virus almost always fail to develop an immune deficiency, whereas primates infected with a nonnative strain tend to develop disease
Age	Infected infants have a higher risk of rapidly developing acquired immunodeficiency syndrome (AIDS). This is less common in adults. What makes one a rapid progressor is not known
Viral setpoint	New research is casting doubt on the long-accepted notion that the higher the setpoint, the shorter the period of clinical latency
Broad and robust cellular and humoral immune responses	These correlate with lower setpoints, but what parts of these and which one is more important are unknown
Co-receptor mutations: $\Delta 32$ CCR5, CCR2-64I, SDF 1-3' A	Homozygotes for the $\Delta 32$ CCR5 mutation fail to develop disease, heterozygotes have a much longer period of clinical latency
Th1 responses: IL-2 and interferon- γ levels	Found in subsets of long-term nonprogressors
Autoantibodies to CCR5	
HLA-B27, -B57, -DR	
APOBEC3G levels	Higher levels are associated with slower progression
Viral fitness	Less fit viruses are associated with slower progression

positive, a second confirmatory test is done. This is usually a Western blot or a radioimmunoassay (RIA), which has a higher specificity than the ELISA, but requires a more specialized laboratory setting. The first-generation ELISAs were based on detection of HIV-1-specific IgG. They have been in widespread use for some time and are well validated. The third generation of ELISAs are designed to detect both HIV-1- and HIV-2-specific IgG and IgM. This allows one test to detect both types of HIV and also the earlier-appearing specific IgM antibodies. A fourth generation of ELISAs has the additional capacity to detect HIV antigens in patient sera, as well as antibodies. It allows the detection of viral particles in acute HIV infection when the viremia is high, but antibodies have not yet developed. An interesting additional use of the ELISAs is to record the actual antibody titers and their avidity. Studies have correlated titer and avidity to indicate duration of infection: lower titers and lower antibody avidity indicate more recent infection.

Several alternative methods of testing for HIV infection have emerged in recent years. Rapid tests can be performed in 30 minutes or less. They are simple, self-contained devices based on immunochromatography. In these tests, a sample of the patient's serum is placed on the tip of the device. As the sample diffuses through the paper substrate, it diffuses through the reagents necessary to produce a color reaction, indicating a positive or a negative result. These assays are advertised as being as sensitive and specific as ELISAs; they therefore need confirmation by a Western blot or RIA if positive. Other variants of this test are assays that use saliva or urine to diagnose HIV. Although these have been licensed by the Food and Drug Administration for use in diagnostic laboratories, none has yet been licensed for home use. However, they may offer excellent diagnostic options for clinicians in resource-poor settings.

Confirmatory testing with a Western blot is the gold standard. Interestingly, up to 15% of noninfected sera will have some reactivity on

KEY CONCEPTS

INTERPRETATION OF WESTERN BLOTS (WB)

- >> Repeatedly reactive WB: patient is infected and highly active antiretroviral therapy (HAART) should be discussed, keeping in mind the likelihood of disease progression based on clinical, immunologic, and virologic criteria
- >> Indeterminate: either a false positive or an early infection; repeat test in 3 and 6 months: if positive, then discuss HAART as above; if negative or still indeterminate, likely not infected
- >> Unreactive: not infected

the Western blot, usually to the Gag proteins. A positive result has been defined as reactivity to two or more of the following: p24, p41, gp120/160. Reactivity to other bands is interpreted as an indeterminate result. A negative result is defined as no reactivity to any of the antigens. Indeterminate results indicate either a patient who will with time seroconvert to a full positive (i.e., an individual recently infected) or someone who will never convert to a full positive (i.e., a noninfected individual). Serial monitoring of the Western blot over the course of 6 months is recommended for indeterminate results. If after that period of time they are still indeterminate or have reverted to nonreactive, the patient can be assumed to be uninfected with HIV. Obviously, if the patient has manifestations of HIV disease, he or she was likely to have been infected at the time of the initial test. Usually, Western blots are performed on the same specimen as the positive HIV ELISA. Positive tests should be

repeated on a second specimen to confirm infection in a particular patient or be confirmed with a positive viral load test.

In newborn children, maternal antibodies persist for up to 18 months of age, invalidating the use of serum ELISAs and Western blots to diagnose HIV infection in children less than 18 months of age. In infants born to HIV-infected mothers, HIV DNA polymerase chain reaction (PCR) tests should be checked within the first week of life and at 1–2 months and 4–6 months of age. Two negative tests are required to exclude infection. A positive result should be confirmed through a repeat study. There are two types of neonatal HIV infection: *in utero* infection and intrapartum infection. *In utero* infection is defined by a positive HIV PCR or viral culture within the first 48 hours of life, implying established infection by the time of birth. Intrapartum infection represents the majority of neonatal HIV infections. In these cases, confirmatory tests will document HIV infection only after 1 week of life. Infants who have negative HIV DNA PCR results should then have an HIV ELISA performed at 12–18 months of age to document loss of maternal antibody.

MONITORING TESTS

Once infection is confirmed, CDC guidelines recommend periodically checking the viral load by quantitative RNA PCR, CD4 T-cell levels, and a genotype assay. Genotype assays are based on PCR and genomic sequencing and they identify the presence or absence of key mutations that confer anti-HIV drug resistance. Other assays that can be ordered are phenotype and viral fitness assays. Phenotype assays are performed by isolating certain key regulatory genes from HIV, usually protease and RT, inserting them into a standardized viral construct containing an indicator cassette, and infecting cell lines in the presence of antiretroviral agents. The results are compared against control viral isolates and expressed as a fold-change in viral susceptibility. This provides similar information to the genotype assays, but does so in a direct way, somewhat similar to bacterial antimicrobial sensitivity results. Genotype data are used to extrapolate the resistance patterns of viruses, whereas phenotype data directly measure them. A virtual phenotype test is an extrapolated phenotype study based on comparing the genotype to known phenotypes in the test manufacturer's database. Studies have indicated that the virtual phenotype test is as good as a "real" phenotype test. While phenotyping is a useful predictor of viral susceptibilities to antiretroviral agents, large studies have failed to prove conclusively a clinical benefit of phenotypes over genotypes.

One additional test that is commercially available, but not widely used, is the viral fitness assay, which is similar to the phenotype assay in that it involves isolating viral genes of interest, incorporating them into a viral construct with an indicator cassette. However, unlike the procedure with phenotype test, the resulting viral particle is not cultured with cells in the presence of antiretroviral agents. The rate or amount of infection induced by the viral particles is compared against a wild-type virus and expressed in terms of a percent infectivity compared to the wild-type virus. Therefore, a virus that is more infectious, and presumably more pathogenic, than wild-type virus would have a value > 100% and, similarly, a virus that is less infectious and presumably less pathogenic would have a value < 100%. This assay is an attempt to quantify the loss in fitness that resistance mutations induce in HIV, with the thought that there may be an advantage in promoting the continuing presence of certain mutations in circulating viral strains.⁴¹

KEY CONCEPTS

OTHER HUMAN IMMUNODEFICIENCY VIRUS (HIV) TESTS

- >> Genotyping: helps to guide the choice of antiretrovirals in patients with resistant virus by sequencing the viral genetic code and identifying mutations, which confer resistance to specific agents or classes of agents
- >> Phenotyping: similar information to genotyping but not widely used; based on growing engineered viruses with a patient's virus' genes in the presence of antiretrovirals to determine their resistance
- >> Viral fitness: the newest and least utilized assay is based on the phenotype assay except that it grows the virus without antiretrovirals to measure its intrinsic replicative capacity relative to a defined wild-type virus; no large clinical trials have validated its superiority to existing tests
- >> All three of these assays present data as if there is only one virus strain in the body; in reality there are numerous viral strains at any one time, with many more archived in cells; these assays detect the dominant strain in the circulation, neglecting the other strains which may account for up to 20% of the circulating viral particles. Given this limitation, when genotyping results are utilized for changing therapy, old treatment regimens and previous genotype results must be taken into consideration

TREATMENT

INITIATION OF THERAPY

The decision to begin treatment for HIV-infected patients is currently a matter of controversy. Experimental studies showing the extent of immune destruction in the gastrointestinal mucosa early in the infection have supported those who advocate starting therapy as soon as the patient is diagnosed. However, these same studies indicate that the destruction of the mucosal CD4 T-cell compartment is not complete in the acute stages of infection. Most patients are not diagnosed during the acute infection, but rather much later in the course of the disease. Early antiretroviral drug treatment results in early development of viral resistance to drugs and medical complications secondary to the drugs' side effects. US treatment guidelines recommend starting therapy when the patient: (1) develops an AIDS-defining illness; (2) has a CD4 T-cell count of < 350 cells/mm³; (3) or has a viral load of > 100 000 copies/ml. Patients with > 350 CD4 T cells/mm³ or with viral loads < 100 000 copies/ml who are asymptomatic can be monitored without therapy.⁴² In children < 12 months of age, US guidelines recommend initiating therapy in any symptomatic child or in a child with < 25% of CD4 T cells. Additionally, consider initiating treatment in any HIV-infected child < 12 months of age, since the disease tends to progress more rapidly in infants than in older children or adults.⁴³ For children older than 12 months, the guidelines recommend initiating therapy when children have AIDS or a CD4 T-cell percentage < 15% and to consider therapy in children with mild to moderate symptoms or 15–25% CD4 T cells

or > 100 000 copies/ml of viral RNA. At any age, medication adherence issues must be addressed first. Nonadherence will lead to drug resistance and the potential loss of therapeutic options. The use of levels of viremia to initiate treatment has always been an option in the therapeutic guidelines, and not a mandate, primarily due to concerns for its predictive value in determining the rate of CD4 T-cell decline.

ANTIRETROVIRAL AGENTS

An in-depth discussion of the treatment of HIV is beyond the scope of this chapter. Generally, HIV treatment is based on antiretroviral therapy or HAART using multiple drugs, in an effort to reduce or even eliminate the chance of drug resistance and suppress HIV replication to undetectable levels. Therapy usually consists of two nucleotide RT inhibitors (NRTI) plus a protease inhibitor, or two NRTIs plus a nonnucleoside RT inhibitor (NNRTI).

There are four classes of antiretroviral agents currently available: NRTIs, NNRTIs, protease inhibitors, and a fusion inhibitor (Table 37.9). NRTIs once tri-phosphorylated *in vivo* become analogues of native nucleotides and as such are able to be incorporated into the proviral DNA by HIV RT. Once part of the proviral DNA, they induce premature chain termination as they lack the 3'-hydroxyl group on the

ribose moiety and thus inhibit successful conversion of the viral RNA to DNA (Fig. 37.10). NNRTIs act at the same step of the viral lifecycle as NRTIs; however, they act by binding to RT and inducing a conformational change such that RT is unable to bind with nucleotides. Protease inhibitors act on viral protease, preventing the cleaving of the viral polyproteins necessary for maturation and infectivity of viral particles. Fusion

THERAPEUTIC PRINCIPLE

USE OF NEWER AGENTS

- >> Fusion inhibitors must be given parenterally and are poorly tolerated by patients. The approved fusion inhibitor is used primarily in salvage regimens for multidrug-resistant viruses
- >> Newer agents will likely also begin as salvage regimens. However, early studies of integrase inhibitors show similar efficacy to nonnucleoside reverse transcriptase inhibitors. If well tolerated and efficacious, newer agents may advance to being first-line therapy

Table 37.9 US Food and Drug Administration-approved antiretroviral agents

Generic name	Abbreviation	Brand name	Generic name	Abbreviation	Brand name
Nucleoside reverse transcriptase inhibitors (NRTIs)			Nonnucleoside reverse transcriptase inhibitors (NNRTIs)		
Zidovudine	AZT, ZDV	Retrovir	Nevirapine	NVP	Viramune
Didanosine	Ddl	Videx	Delavirdine	DLV	Rescriptor
Zalcitabine	DdC	Hivid	Efavirenz	EFV	Sustiva
Stavudine	d4T	Zerit	Protease inhibitors		
Lamivudine	3TC	Epivir	Saquinavir	SQV, hgc SQV, sgc	Invirase Fortovase
Abacavir	ABC	Ziagen	Ritonavir	RTV	Norvir
Tenofovir DF	TDF	Viread	Indinavir	IDV	Crixivan
Emtricitabine	FTC	Emtriva	Nelfinavir	NFV	Viracept
Fusion inhibitor			Amprenavir	APV	Agenerase
Enfuvirtide	T-20	Fuzeon	Atazanavir	ATV	Reyataz
Combination pills			Tipranavir		Aptivus
Efavirenz Tenofovir DF and emtricitabine		Atripla	Darunavir		Prezista
Zidovudine and lamivudine		Combivir	Fosamprenavir		Lexiva
Abacavir and lamivudine		Epzicom	Lopinavir and ritonavir		Kaletra
Zidovudine lamivudine and abacavir		Trizivir			
Tenofovir DF and emtricitabine		Truvada			

Fig. 37.10 Lifecycle of human immunodeficiency virus (HIV) and the sites of action of antiretroviral agents: HIV binds to CD4 and its chemokine co-receptor (CCR5 and CXCR4). The viral particle is then uncoated and reverse transcription takes place. The viral DNA is then transported to the nucleus where it integrates with the host DNA. Through transcription and translation, the viral genome is copied for either packaging into new virions or for production of viral proteins. The genome and proteins are transported to the cell membrane where they are incorporated into budding viral particles. Following release, maturation occurs to create an infectious virion. Classes of antiretroviral agents are listed below the steps where they act. RT, reverse transcriptase; NRTI, nucleotide RT inhibitors; NNRTIs, nonnucleoside RT inhibitors.

inhibitors are the newest licensed class of anti-HIV medications. The currently available agent acts to block the conformational changes in gp41 necessary to induce fusion of the viral particle with the host cell. Drugs in development include various molecules acting at the steps of entry and fusion, integrase inhibitors, maturation inhibitors, and topical microbicides (Table 37.10). New research suggests that a component of green tea, epigallocatechin gallate or EGCG, can bind to the D1 domain of CD4 and sterically prevent HIV gp120 from binding (Fig. 37.11).⁴⁴

IMMUNORECONSTITUTION AFTER HAART THERAPY

To varying degrees, the immune system is able to recover following initiation of therapy, a process called immunoreconstitution.⁴⁵ Upon starting HAART in patients who are compliant and able to tolerate the regimen, the initial CD4 T-cell count is the best predictor of a successful outcome. Patients' viral loads are the first to respond following initiation of HAART, often rapidly becoming undetectable. This reflects the medications' ability to repress viral replication rapidly. Lagging behind the drop in viral load is the rise in CD4 T cells. An initial increase in circulating cells occurs in 3–6 months as a result of a decrease in immune activation and subsequent migration of memory T cells (CD4⁺CD45RO⁺) out of the lymphoid compartment. A more gradual rise in total CD4 T cells occurs over the course of 3–5 years with the appearance of new naïve (CD4⁺CD45RA⁺CD62L⁺) and memory T cells. Interestingly, a substantial minority of patients never reach a normal level of CD4 T cells,

plateauing at a lower level. Primary and some secondary drug prophylaxis for opportunistic infections can be safely discontinued in patients once the CD4 T-cell count is > 200 cells/mm³ for more than 3–6 months. Cellular and humoral responses to most pathogens also recover with rising counts. Of interest, a low CD4 T-cell count at the time of initiating HAART predicts a poor response to bacterial vaccines given after recovery of CD4 T-cell levels, suggesting a lag in the return of naïve CD4 T cells.

SCHEDULED TREATMENT INTERRUPTIONS

Scheduled treatment interruptions (STIs) were originally proposed as a way to 'auto-vaccinate' the host immune system against HIV, with the hope that stronger cellular and humoral immune responses could be elicited. It was speculated that these immune responses could result in a lower setpoint or even sustained viral suppression off HAART. While initial studies showed promise, larger studies failed to show sustained viral control and were associated with adverse events, such as a higher rate of oral candidiasis. The Staccato trial was a large randomized trial addressing STI with three arms: a 1-week-on and 1-week-off arm, an arm guided by CD4 T-cell counts in which treatment would start only when counts dropped below 350 cells/mm³, and a continuous-treatment arm.⁴⁶ The 1-week-on/1-week-off arm was discontinued prematurely as there was a high rate of failure when compared to the other arms. The remaining two arms, however, demonstrated that there was no significant difference between CD4 T-cell-guided treatment versus continuous treatment in terms of virologic response and presence of drug resistance mutations. Obviously, there was a significant difference in cost and expenses between the groups. The incidence of thrush was higher in the STI group versus the continuous-treatment arm, but the incidence of treatment-related side effects was less in the STI cohort than the other. The authors point out that the Staccato trial was not powered to detect differences in mortality or the incidence of AIDS-defining illnesses; needless to say, their data support continued studies into STI. Subsequently, a larger Strategies for Management of Antiretroviral Therapy (SMART) trial failed to demonstrate a benefit or even parity between its STI and the continuous-treatment cohorts.⁴⁷ It demonstrated an increased incidence of opportunistic illnesses and deaths in the STI group and was stopped early. One key difference is that the SMART trial withheld HAART until the CD4 T-cell count dropped below 250 cells rather than the 350 benchmark utilized in the Staccato trial.

IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME

Immune reconstitution inflammatory syndrome (IRIS) is a well-known, if incompletely understood, response in AIDS patients with very low CD4 T-cell counts who begin HAART.⁴⁸ It is felt to be an inflammatory response by the rebounding host immune system to opportunistic infections, similar to the paradoxical immune response in tuberculosis or leprosy patients after starting antibiotic treatment. Other thoughts as to the etiology include a proinflammatory state secondary to "asymmetric" recovery of the immune system. In other words, there is a proinflammatory state, due to either increased secretion of proinflammatory cytokines or an imbalance between regulatory and effector cells. Risk factors

Table 37.10 Investigational agent in clinical trials^a

Drug class	Name	Comments
Entry and fusion inhibitors	AMD070	CXCR4 inhibitor

Fig. 37.11 Epigallocatechin gallate (EGCG) binding to CD4: Recent studies indicate that EGCG, a component of green tea, can bind to the human immunodeficiency virus (HIV) binding site of CD4 and potentially interfere in viral infection. (From Williamson MP, McCormick TG, Nance CL, et al. Epigallocatechin gallate, the main polyphenol in green tea, binds to the T-cell receptor, CD4: potential for HIV-1 therapy. *J Allergy Clin Immunol* 2006; 118: 1369–1374, with permission from the American Academy of Allergy, Asthma and Immunology.)

CLINICAL PEARL

IMMUNORECONSTITUTION INFLAMMATORY SYNDROME (IRIS)

- >> IRIS is typically found 2–3 weeks after initiating highly active antiretroviral therapy (HAART)
- >> Patients often become profoundly ill and require hospitalization
- >> Steroids are sometimes useful in the treatment
- >> Clinicians may prevent IRIS by initiating HAART only after treating opportunistic infections

include: (1) low CD4 T-cell counts or high viral loads at the time of initiating HAART; (2) duration of immunosuppression; (3) active opportunistic infections; and (4) rapid increase in CD4 T-cell counts. Some genetic factors implicated in IRIS include certain HLA haplotypes (HLA-B27, -Cw0202, -DR4; HLA-A2, -B44; and HLA-A1, -B8, -DR3 with TNF- α polymorphisms), and polymorphism in cytokine genes like TNF- α , IL-6, and IL-12.⁴⁹ Studies suggest that between 15% and 25% of patients started on HAART will develop IRIS within 3 months. Treatment includes steroids or other immunosuppressants and treating the opportunistic infections. Clinicians try to prevent IRIS by delaying initiation of HAART in a patient with an opportunistic infection until the opportunistic infection has been treated.

An intriguing recent study in children from the Netherlands confirms a fact that many clinicians have long suspected: humoral immune responses to vaccines are abnormal in immune-reconstituted HIV-seropositive children.⁵⁰ The authors demonstrated a failure to respond to

all three components of the measles, mumps, and rubella vaccine in HIV-infected children prior to initiation of HAART, in accord with prior studies. Following initiation of HAART and immune reconstitution, they demonstrated a loss of specific IgG against measles, mumps, and rubella of 40% to 11%. They also detected a loss of measurable IgG against varicella-zoster virus and herpes simplex virus. They attributed these findings to a persistent dysfunction in memory B cells in infected children. Similar studies point out failure in a substantial minority of patients to restore their CD4 T-cell compartment to normal levels in spite of undetectable HIV RNA. This result may indicate continuing levels of apoptosis or virus-induced cell death or from insufficient thymic reserve to repopulate the compartment completely. Preliminary studies show that giving IL-2 increased the survival of CD4 T cells from almost 2 weeks to almost 29 weeks.⁵¹

Another complication possibly associated with IRIS is the appearance of an asthma-like condition in perinatally HIV-infected children, who were given combination antiretroviral therapies since infancy. This condition may be mediated by CD4 T-cell activation, release of Th2-type cytokines, and loss of T regulatory cells and tolerance.⁵² In support of this concept, Lin and Lazarus had previously observed that a CD4 T-cell count of > 200 cells/ μ l in the blood of HIV-infected adults was significantly associated with concurrent asthma.⁵³

PREVENTION

As a cure to the epidemic remains elusive, prevention remains crucial to a fundamental part of the world's HIV control strategy. These methods include using condoms, providing IDUs with free sterile needles, screening blood products, administering antiretrovirals to pregnant women and their infants, and providing health care workers with antiretroviral agents after occupational exposure. From an immunologic standpoint, several areas of prevention are worth discussing, including vaccines and topical agents.

MICROBICIDES

Topical microbicides have begun to generate increasing interest within the HIV community. They offer simple, noninvasive methods of controlling the spread of HIV that can be used on an as-needed basis. Topical microbicides are a targeted intervention to reduce the risk of transmission during heterosexual intercourse in areas such as sub-Saharan Africa, where the risk of contracting HIV is high, but the desire to use condoms is low. Specifically, this allows women to use anti-HIV agents that reduce their risk of infection in cultures where they have little control over their sex lives and men refuse to use condoms. One class of agents is those designed to neutralize the virus.⁵⁴ These include detergents and other products that lower the intraluminal pH to < 4.5, the pH at which HIV is inactivated. Another class includes antiretrovirals, with the thought that by directly applying antiretrovirals to the mucosal surface, HIV replication can be stopped after infection occurs, but before it has a chance to spread. The third and largest class of agents includes those designed to block the receptors and co-receptors used by HIV during infection. Several different agents fall within this category. Polyanionic substances disrupt the interaction between the positively charged viral envelope and the negatively charged cell surface. Lectins and monoclonal antibodies are agents that target the glycan shield surrounding the viral

particle, which hides the viral surface proteins from host defenses. However, escape mutants have been found against these agents. A monoclonal antibody directed against the CD4 binding site on gp120 has been developed, as have antibodies and agents against gp41. Monoclonal antibodies directed against CD4 that block HIV-CD4 interactions but not CD4-MHC class II are also under investigation. Antibodies and agents against DC-SIGN prevent dendritic cells from importing and presenting HIV to CD4 T cells; however, their usefulness has been limited in animal studies. Perhaps the most promising topical agents are those that target CCR5 on target cells. These agents induce the internalization of CCR5 or conformational changes, which render CCR5 unable or unavailable to bind to HIV. Without CCR5, R5 viruses are unable to infect CD4 T cells.

PREVENTIVE VACCINES

Vaccines are perhaps the greatest hope for curbing the epidemic. But to date, and despite tremendous resource allocation to study and develop them, no effective candidate vaccine has emerged. Initial attempts at vaccine development focused on the traditional methods of vaccine design: whole killed HIV, HIV protein epitopes, and live-attenuated virus.^{55, 56} Whole killed virus failed to elicit a strong neutralizing antibody response and investigators remained concerned over the risk of incompletely inactivating HIV. HIV proteins are safe and well tolerated, but again failed to induce a strong neutralizing antibody response, even when coupled with adjuvants. A large phase III trial of recombinant gp120 failed to demonstrate protection from HIV infection.

Live attenuated virus vaccines

Live attenuated SIV has protected macaques from viral challenge. Concerns over the safety of attenuated HIV because of potential reversion to wild-type, however, have prevented enthusiasm for further research on live-attenuated viruses. Additional studies have demonstrated that the greater the replication capacity of the live attenuated virus, the greater its protection.⁵⁷ In other words, the more attenuated viruses, which would have greater theoretical safety, are the least protective. Several patients infected with *nef*- and LTR-deficient strains of HIV, i.e., naturally attenuated strains, eventually developed AIDS, as have several macaques infected with attenuated viruses.

DNA vaccines

Attempts at injecting naked DNA plasmids into animals, where they are taken up by cells and used as a template to make specific HIV proteins, proved promising in mice and primates. Human studies have so far been disappointing. One way to boost the immunogenicity of DNA vaccines is to follow them with a replicating viral gene vector, such as a pox virus or an adenovirus. Viral vectors are viruses engineered to express certain HIV proteins. The pox viruses in trials, principally canarypox and vaccinia, are able to elicit robust humoral immune responses, but poor or nondurable cellular immune responses. Additionally, prior immunity to smallpox would prevent the vaccine from working. The adenoviral vectors, mostly based on recombinant adenovirus serotype 5 (Ad5), are able to generate strong cellular and humoral immune responses. They have proven unable to prevent infection in primate models, but have protected animals against the

development of SAIDS when challenged with a homologous virus. How well they would do against a real-world case of challenge with nonhomologous viruses in humans is still under investigation. As with the pox viral vectors, prior immunity to Ad5 determines a blunted immune response to the vaccine in some individuals. Unfortunately, many areas of the world with high pre-existing immunity to Ad5 are also some of the hardest-hit areas from the HIV epidemic. Using DNA vaccine priming followed by viral boosting probably represents the most promising vaccination strategy to date. However, even this strategy has not been able to prevent HIV infection or disease when challenged with nonhomologous viral strains.

Novel vaccines

Other potential vaccine designs include pseudovirions, or virus-like-particles. These are essentially the outer layers of HIV without enough genetic core to be infectious. They allow the immune system to encounter HIV in as realistic a manner as possible, with all the HIV surface proteins existing in the proper confirmations. The importance of this approach is demonstrated by the fact that nonnative, nontrimeric Env is unable to produce neutralizing antibodies, while trimeric Env does induce these antibodies. A final class of agents are replicons, which are similarly engineered replication-defective viruses that express HIV proteins. Ongoing vaccine clinical trials under the auspice of the HIV Vaccine Trials Network are listed in Table 37.11.

An intriguing vaccine approach reintroduced autologous monocyte-derived dendritic cells pulsed *ex vivo* with inactivated HIV in 18 patients.⁵⁸ The authors demonstrated a drop in mean viral loads of 80% within the first 112 days of follow-up. Over the course of a year, 8 patients were able to maintain a > 90% reduction in viral load. High levels of HIV-1-specific IL-2 or IFN- γ secreting CD4 T cells as well as HIV-1 gag-specific perforin-expressing CD8 T cells were associated with improved viral control.

THERAPEUTIC VACCINES

There are two possible forms for an HIV vaccine: a prophylactic vaccine and a therapeutic vaccine. The prophylactic vaccine is the traditional model, where vaccination is able to prevent or circumvent infection, usually through the induction of sterilizing immunity. A therapeutic vaccine is one in which the vaccine is used after infection occurs, aiming to induce antiviral immunity to alter the course of disease. This would be accomplished by controlling viremia or reducing the viral setpoint in infected patients. Primate models suggest that just such a result is possible, especially with cellular immunity-inducing vaccines. To date, however, data from human studies show no conclusive benefit. Using a therapeutic vaccine in combination with HAART is another approach currently under investigation.

A recent study of a therapeutic vaccine demonstrated that vaccination can induce relative sparing of the central memory T cells following challenge with SIV.⁵⁹ Macaques were immunized with a standard recombinant DNA priming vaccine, followed by a boost with a recombinant adenoviral vector vaccine and then challenged with a pathogenic SIV strain. The vaccinated animals initially demonstrated a reduced level of viremia during the acute phase of infection, but over time the viral loads of both the sham-immunized animals and the vaccinated animals' viral loads normalized. Given the similar viral setpoints, one would assume a

Table 37.11 Human immunodeficiency virus (HIV) vaccines in clinical trials^a

Trial name (phase II)	Prime component	Boost component
HVTN 502/Merck 023	Nonreplicating adenoviral vector with clade B Gag-Pol-Nef	
HVTN 204	DNA plasmids: clade B Gag, Pol, and Nef; clade A, B, C Env	Nonreplicating adenoviral vector with clade B Gag-Pol and clade A,B,C Env
Phase I		
HVTN 042/ANRS VAC19	Canarypox vector: clade B, Env, Gag, Pro, RT, Nef	Lipopeptides: clade B Gag, Pol, Nef
HVTN 044	DNA plasmids: clade B Gag, Pol, and Nef; clade A, B, C Env	
HVTN 049	DNA plasmids: clade B Gag, Env	Protein subunit: clade B Env
HVTN 050/Merck 018	Nonreplicating adenoviral vector: clade B Gag

similar outcome for the animals. Intriguingly, this was not the case: vaccinated animals fared better than sham-immunized animals. The researchers noted a significant increase in the proportion of central memory T cells in the vaccinated animals, confirming current theories that loss of memory CD4 T cells during the acute phase of infection plays an important role in the overall pathogenesis of the virus.

The recent Failure of the National Institutes of Health HIV Vaccine Trials Network T-cell vaccine in a 3,000 HIV-negative subject cohort has served to emphasize again the elusive nature of designing a successful HIV vaccine and the need for more research for an HIV vaccine that works.⁶⁰

CONCLUSION

The sudden appearance of HIV in the 1980s and subsequent pandemic reminded clinicians and scientists alike that infectious diseases have not been vanquished or relegated to developing countries. It also served as a reminder that, as the world becomes smaller with increased communication

means, and as populations expand into remote areas, new and potentially deadly pathogens continue to emerge. From a basic science perspective, HIV has demonstrated how little we knew of the structure and mechanisms of the immune system and the differences in immunity between mammal species. HIV continues to impress and baffle researchers. Perhaps as a result of millions of years living and adapting in other primate species, it has developed an impressive arsenal of ways to thwart both our innate and adaptive immune systems. One could even say that it is not just a reactive virus, but one that is proactive, striking at immune cells, the very cells that are designed to control it. Our efforts at designing a vaccine have taught us much about the immunology of HIV, but have not yet developed into a successful candidate. It should be noted, however, that most current vaccines are directed against viruses or bacteria for which the body can mount an effective immune response on its own. Despite all this, immunology has made great strides in our understanding of HIV. Perhaps in no other disease has so much been learned so fast. In the developed world, HIV causes chronic infection rather than certain death, thanks in large part to the use of antiviral drugs. More novel drugs

in development are due to new-found understanding of the molecular biology behind HIV. For virologists and immunologists, HIV continues to perplex and fascinate; for clinicians it continues to teach humility.

Immunodeficiency due to congenital, metabolic, infectious, surgical and environmental factors

Javier Chinen, William T. Shearer

38

The majority of human immunodeficiencies result from factors extrinsic to the immune system, such as malnutrition, immunosuppressive agents, surgery and trauma. In addition, extremes of age (i.e., prematurity and old age), adverse environments (e.g., high altitude, space travel), and genetic conditions may also affect immune function (Table 38.1). Malnutrition, for example, is a significant factor because it affects a large percentage of the population worldwide and renders them susceptible to infection. Early and advanced ages present with increased susceptibility to infections, due in part to physiological changes corresponding to maturation and senescence of the immune response, respectively (Chapters 32 and 33). Some therapeutic agents, including chemotherapeutic drugs, may have immunosuppressive properties (Chapter 90).

In this chapter, selected clinical disorders of genetic (other than primary immune deficiencies), metabolic, and environmental etiology are discussed, conditions that are known to be associated with decreased immune function. These diseases usually cause immune defects that are heterogeneous in presentation, affecting humoral and cellular immunity with variable degrees of severity. Understanding these mechanisms of disease helps in the assessment and management of patients, because correction of the primary disorder, when it is feasible, often leads to prevention or reversal of the related immune defects.

KEY CONCEPTS

- >> Immunodeficiencies commonly occur as the result of diseases or conditions extrinsic to the immune system, such as malnutrition.
- >> Correction of the primary disorder leads to prevention or reversal of the related immune defects.
- >> Environmental conditions, when severe, may induce immunodeficiency by acting as stressors or by suppression of the production and function of immune cells.

IMMUNOLOGICAL DEFECTS ASSOCIATED WITH GENETIC DISEASES OTHER THAN PRIMARY IMMUNODEFICIENCIES

Genetic diseases include a number of rare conditions that range from deleterious mutations in a single gene to deletions or duplications of entire chromosomes. These conditions can be inherited from the patients' parents or they can appear 'de novo' in a particular individual. There are several, albeit very rare, genetic syndromes that can be associated with mild to moderate degrees of immune compromise. The pathogenesis of the immune defects in these syndromes is hypothesized to include deficiency of proteins such as cytokines and adhesion molecules, the loss of continuity of natural epithelial barriers, and subtle defects in cell division and DNA repair. The management of increased susceptibility to infections in patients with genetic diseases relies on prevention, by promoting hygiene measures and using antibiotic prophylaxis when necessary. The most common genetic syndromes with described secondary immunodeficiency are discussed.

DOWN'S SYNDROME

Down's syndrome (DS) or trisomy of chromosome 21 is a relatively common congenital defect with an incidence of 1:600–1:800 live births. DS patients present with hypotonia, characteristic facies, heart and gastrointestinal defects and mental retardation. Infections are common but usually not severe, such as periodontitis and upper respiratory tract infections. Although the risk of frequent infections can be attributed to poor hygiene and institutionalization, immunological abnormalities have been reported, including absolute lymphopenia and a decreased number of naïve T cells,¹ possibly secondary to premature thymus involution. Also, impaired antibody response has been demonstrated, which could be associated to IgG subclass deficiency. Phagocytic cells from DS patients show decreased chemotaxis, phagocytosis and bacterial killing. Autoimmune disease occurs at a higher frequency in DS, with its most

Table 38.1 Common conditions associated with secondary immunodeficiencies

	Cellular immunity	Humoral immunity
Congenital		
Down's syndrome	T cell cytopenia, decreased LPR to mitogens, thymus hypotrophy, decreased naïve T cells, defective NK-cell activity, decreased phagocytosis and chemotaxis	Decreased antibody response to vaccines, increased autoimmune antibodies
Turner's syndrome	T-cell cytopenia, anergy, poor LPR to mitogens	Decreased serum IgG and IgM levels
Metabolic		
Protein-calorie malnutrition	T-cell cytopenia, thymus hypotrophy, impaired cytokine secretion, decreased chemotaxis and phagocytosis	Poor antibody response to vaccines, elevated serum IgA levels, decreased serum IgG levels
Diabetes mellitus	T-cell cytopenia, decreased LPR to mitogens, decreased chemotaxis and phagocytosis.	Decreased antibody response to vaccines
Nephrotic syndrome	T-cell cytopenia, anergy, poor LPR to mitogens	Decreased serum IgG levels and response to vaccines
Uremia	Increased T-cell apoptosis, lymphopenia decreased LPR to mitogens, decreased chemotaxis and phagocytosis, decreased oxidative response.	Decreased serum IgG levels and response to vaccines
Infectious diseases		
HIV infection	CD4 T-cell cytopenia, decreased LPR to mitogens and antigens, decreased DTH, decreased naïve T cells, thymus hypotrophy. Poor NK cell and phagocytic activity	Poor antibody responses, increased serum IgG levels.
Viral infections – measles	Impaired antigen presentation, cell-mediated killing	Decreased serum IgG levels, decreased antibody responses
Stress		
Trauma	T-cell cytopenia, depressed DTH, decreased chemotaxis.	Decreased complement activity
Splenectomy	Not reported	Poor antibody responses, negligible to polysaccharides
Environmental conditions		
Radiation and UV light	T-cell anergy, poor antigen presentation, severe immunosuppression at high doses	Defective response secondary to impaired cellular immunity
High altitude	T- and NK cell cytopenia	Decreased serum IgG level
Space flight	Lymphopenia, decreased LPR to mitogens, decreased NK cell activity and cytokine secretion (IL-10, IL-1a).	Normal in a space flight model
LPR, lymphoproliferative response; DTH delayed-type hypersensitivity.		

frequent manifestation, thyroiditis, developing before 8 years of age in about half of children with DS.² Recently, it has been reported that mononuclear cells from DS patients have increased expression of DSCAM (Down's syndrome cellular adhesion molecule) and SOD1 (superoxide dismutase 1), two proteins encoded in genes located in chromosome 21, which could explain impaired pathogen clearance.³ Decreased institutionalization and better access to medical care have reduced the risk of infection and improved the life expectancy of DS patients.

TURNER'S SYNDROME

Turner's syndrome (TS) results from the presence of only one X chromosome, the other being missing or abnormally repressed. TS patients have short stature, do not develop into puberty, and are infertile. They present with frequent respiratory infections and develop bronchiectasis at an early age. However, there are no consistent immune defects in all TS patients. Low immunoglobulin levels⁴ and decreased T-cell proliferative responses to mitogens⁵ have been shown in some patients.

CLINICAL PEARLS

- >> Sickle cell disease (SCD) patients have increased susceptibility to infections with encapsulated organisms, such as *S. pneumoniae*.
- >> Autosplenectomy occurs in most SCD patients by 2 years of age, and is associated with poor antibody response to polysaccharide and inefficient complement activity.
- >> Prevention of infections in SCD patients includes completion of routine immunizations and anti-pneumococcal antibiotic prophylaxis.

SICKLE CELL DISEASE

Two genetic diseases with a significant prevalence in the general population and with increased susceptibility to infections are sickle cell disease (SCD) and cystic fibrosis (CF). SCD is an autosomal recessive disease that affects the expression of the β -hemoglobin protein and causes anemia. Its prevalence is highest in African Americans at 1:500. SCD patients have an increased susceptibility for infections from encapsulated organisms: for example, *Streptococcus pneumoniae*-related sepsis and meningitis occur 30–300 times more often than in normal children. As a result of microinfarcts, auto-splenectomy occurs in most SCD patients by the second year of life, and is the major reason for the increased risk of infections, owing to the association between absence of the spleen and impaired antibody production to polysaccharides and a defective complement alternative pathway.⁶ SCD patients also present with an increased frequency of osteomyelitis caused by *Salmonella* sp., although it is not well understood why susceptibility to this pathogen is increased. Prevention of infections in SCD patients should include anti-pneumococcal prophylaxis and routine immunizations to encapsulated organisms. These measures reduce the incidence of pneumococcal infections by at least 84%.⁶

CYSTIC FIBROSIS

CF is an autosomal recessive disorder caused by mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene. It decreases the fluidity of secretions, causing blockade of secretory tubes and affecting organs such as the pancreas, salivary glands, gonads, and liver. Most significantly, the mucociliary clearance of bacteria in the lungs is impaired. CF patients often present with lungs colonized with *Pseudomonas aeruginosa*, or with pneumonia due to this pathogen and other bacteria. Several lung bactericidal factors are decreased, such as lysozymes, defensins and cathelicidins.⁸ This results in poor ability to clear bacterial colonization, and eventual progression to pneumonia. The adaptive immunity is intact, demonstrated by the normal production of antibodies against *P. aeruginosa*.⁷ CF patients experiencing recurrent pneumonias benefit from respiratory therapy to clear secretions and the use of antibiotic prophylaxis.

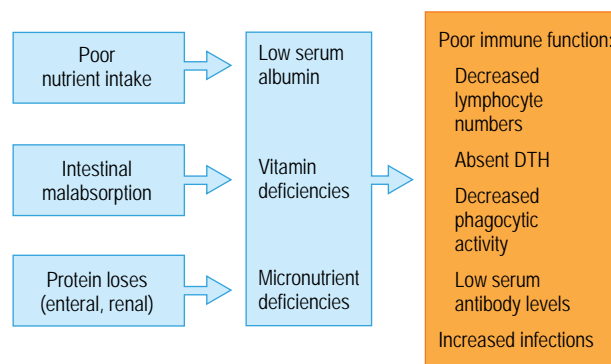

Fig. 38.1 Malnutrition results from poor access to food, decreased absorption of nutrients or loss due to inflammatory enteropathies or renal disease. Protein deficiency causes decreased production of immune cells and immunoglobulins, which increases susceptibility to infection.

IMMUNOLOGICAL DEFECTS SECONDARY TO METABOLIC DISEASES: MALNUTRITION, DIABETES MELLITUS AND UREMIA

Severe malnutrition resulting in depletion of protein, calories and micro-nutrients is associated with increased morbidity and mortality from infections. Other conditions affecting the adequate absorption and metabolism of nutrients, such as diabetes mellitus and protein-losing enteropathy, impair the functioning of all organs, including the immune system.

MALNUTRITION

Malnutrition is one of the most frequent causes of secondary immunodeficiency, affecting individuals of all ages (Fig. 38.1). Protein-calorie malnutrition may result from poor intake, malabsorption or excessive loss of nutrients. Individuals with protein-calorie malnutrition progressively lose T-cell production⁸ and function,⁹ resulting in immunodeficiency with an increased incidence of diarrhea and respiratory infections. These conditions are complicated by a concomitant deficit of micronutrients (e.g., zinc) that augment the susceptibility of infections by inducing defects in the barrier mucosae.¹⁰ Serum immunoglobulin levels appear to remain normal for a relative prolonged period, as does the effectiveness of vaccination to elicit antibodies.^{10, 11} Nutritional replenishment in malnourished children results in reversal of deficiencies of lymphocyte proliferation and phagocytosis, and significant recovery of thymus size by ultrasonography.¹²

Micronutrient deficiencies are more prevalent in protein-calorie malnutrition but may also present alone, usually subclinically in a healthy-looking child. Feeding only half the recommended intake of iron, zinc, or vitamins B, C and E leads to oxidative damage and DNA breaks, with decreased NK-cell cytotoxicity and monocyte phagocytic activity^{13, 14} (Table 38.2).

Table 38.2 Immune defects in micronutrient deficiencies

	Cellular immunity	Humoral immunity
Vitamin A deficiency	T cell cytopenia, decreased DTH, decreased phagocytic and NK-cell function	Lower antibody response to immunization
Vitamin E deficiency	Decreased oxidative activity of phagocytes, increased PGE ₂ secretion (inhibitory)	Increased IgE
Vitamin C deficiency	Decreased phagocytic activity and oxidative response to ingested organisms	Not reported
Zinc deficiency	Lymphopenia, thymus hypotrophy, decreased DTH	Decreased T cell-dependent antibody responses
Iron deficiency	T-cell cytopenia, thymus hypotrophy, decreased phagocytosis	Decreased serum IgG levels
Copper deficiency	Lymphopenia and neutropenia	Not reported
Selenium deficiency	Decreased oxidative response in phagocytes and NK cells	Not reported

DTH, delayed-type hypersensitivity; PGE₂, prostaglandin E₂.

Vitamin A deficiency is manifested by night blindness, dry and scaly skin, apathy, anemia, retarded growth, elevated intracranial pressure and increased infections. Vitamin A deficiency leads to impaired mucous membranes¹⁵ and decreased interferon (IFN)- α production. Higher immunization rates are seen when vitamin A is given with measles vaccine in malnourished children.¹⁶

In contrast to protein-calorie deficiency due to other causes, malnutrition resulting from eating disorders, such as anorexia nervosa and bulimia, does not result in an increased frequency of infections.^{17, 18} However, patients with these disorders show leukopenia and lymphopenia with abnormal delayed-type hypersensitivity responses. Paradoxically, infections may occur during nutritional treatment, possibly because of reactivation of latent infections.

Protein-losing enteropathy can be present in most patients with intestinal inflammatory diseases, and results in hypogammaglobulinemia; however, the ability to produce antibodies is usually preserved. Thus, the need for intravenous immunoglobulin needs to be carefully assessed, because correction of the primary defect can reduce the susceptibility to infection without requiring any other intervention. A similar disorder, intestinal lymphangiectasis, is characterized by congenital intestinal lymphatic obstruction and loss of lymph, with hypogammaglobulinemia and moderate to severe lymphopenia. A diet enriched with medium-chain triglycerides reverses the symptoms and pathological findings.¹⁹

DIABETES MELLITUS

Diabetes mellitus (DM) is characterized by insufficient production of insulin by the pancreas, which results in poor glucose cell metabolism. DM can result from autoimmune damage (type I, insulin dependent) or a decrease in the cell response to insulin (type II, noninsulin-dependent). Both types present with increased susceptibility to infections due to immune defects, poor glucose metabolism, poor blood supply and local denervation. Altered immune defects that have been reported include

lymphopenia, cutaneous anergy, and impaired *in vitro* lymphocyte proliferation.²⁰ The humoral response usually remains intact, with normal antibody responses to routine immunizations. Diabetics can exhibit abnormal phagocytic adherence, chemotaxis, phagocytosis and bactericidal activity.²¹ Maintenance of blood glucose levels in the normal range results in an improvement in phagocyte function and a lower risk of infections.²²

UREMIA

Treatment of uremia often requires either hemodialysis (HD) or peritoneal dialysis. Unfortunately, both uremia and dialysis can induce negative effects on the immune system, and can predispose patients to serious infections. Uremics have a 6–16-fold higher incidence of tuberculosis than nonuremic matched controls.²³ Sepsis secondary to vascular device or respiratory infections are common in dialysis patients. The dysregulation of their immune system is characterized by immunodeficiency with a state of cellular activation, leading to a chronic inflammatory state and increased oxidative stress.²³ Several toxins targeting phagocytes have been identified in the plasma and peritoneal fluid of uremic patients, including angiogenin, p-cresol, a form of ubiquitin, degranulatory inhibitory protein, and a protein with homology to immunoglobulin light chains. Phagocytic cell dysfunction is the most common and consistent immune defect found in uremic patients. Diminished chemotaxis, phagocytosis, intracellular killing and oxygen radical production have been documented.²⁴ The molecular mechanisms of these processes are not clear. It has been suggested that the increased intracellular calcium seen in end-stage renal disease could impair phagocytosis. Iron overload in HD patients is associated with decreased phagocytic bacterial killing and an increased risk of infection.²⁵ Improvement of such immune defects is seen after iron chelation. Decreased lymphocyte counts, depressed lymphoproliferative response to mitogens and antigens, and cutaneous anergy can also be seen in uremic patients. Impaired antigen presentation by monocytes may underlie

the abnormal immune responses. Most uremic patients show an adequate response to vaccines; however, antibody titers decline rapidly within 6 months, regardless of vaccination.²³

■ IMMUNOLOGICAL DEFECTS SECONDARY TO INFECTIOUS DISEASES ■

During the encounter between a microbial pathogen and its host a variety of complex biological processes occur, in which microbes attempt to proliferate and the host fights to eliminate them. Pathogens may interfere with a variety of immunological defenses in order to decrease their clearance and establish an infection.²⁶ In some cases, this action also favors infection by other pathogens. For example, during influenza infection the inflammatory response in the lung paradoxically increases the patient's susceptibility to bacterial pneumonia.²⁷ One infectious agent in particular, human immunodeficiency virus (HIV), targets the immune system itself by infecting CD4 T lymphocytes and causing severe immunodeficiency (Chapter 37). However, most immunological disturbances caused by microbial infections are transient and usually reflect a normal immune response rather than a weakening of the immune defenses. In some cases of chronic infection, such as tuberculosis and parasites, immune suppression may be secondary to the state of wasting induced by these diseases. The following examples describe selected individual pathogens that characteristically induce immune suppression.

VIRAL PATHOGENS

Measles virus. In the early 1900's, it was noted that the tuberculin skin response was blunted during acute measles infection. Measles infects lymphoid tissues through the CD46 molecule, a complement receptor present in monocytes and lymphocytes, affecting antigen presentation, cell-mediated killing and immunoglobulin synthesis.²⁸ The period of immunosuppression lasts only a few weeks until the virus is cleared, but may linger in some hosts. In rare cases, persistent measles infection develops and causes subacute sclerosing panencephalitis, a progressive degeneration of the central nervous system, mediated by an inflammatory reaction triggered by persistent measles antigen, despite the presence of high levels of anti-measles antibodies.

Epstein-Barr virus (EBV)

EBV infection is present in almost 90% of the world's adult population and usually occurs subclinically. It may occasionally manifest as a self-limiting lymphoproliferative disease known as acute infectious mononucleosis. EBV targets B cells using the CD21 surface antigen and transforms them to establish a chronic infection. EBV-infected B cells fail to undergo apoptosis. Activated (also called 'atypical', because of their morphology) T cells eliminate EBV-infected B cells, developing a massive expansion of a selected oligoclonal population with limited TCR V β gene usage. As a result, there is a relative T-cell anergy, which can be demonstrated in *in vitro* experiments. There is also a concurrent polyclonal expansion of B cells with enhanced immunoglobulin production.²⁹ These changes last for only a few weeks.

The X-linked recessive lymphoproliferative syndrome (XLP) develops in individuals with mutations in the *SH2L1A* gene, resulting in affected males being unable to control EBV-infected cell proliferation. Impaired immune response, splenomegaly and lymphoproliferative disease are usually fatal to the patient.³⁰

Cytomegalovirus (CMV)

Infection with CMV also leads to a mononucleosis illness. CMV-infected monocytes have a decreased ability to present antigens because of reduced MHC protein expression and function, and the presence of viral molecules that resemble MHC proteins. In addition, CMV encodes a human IL-10 homolog which has been demonstrated to inhibit the activation of human lymphocytes.³¹

Influenza virus

Acute infection with influenza virus causes lymphopenia, primarily within the T-cell population. Other immunological alterations are reduced lymphocyte proliferation, increased NK-cell activity and increased generation of regulatory T cells, as well as impairment of mucus clearance that enhances bacterial adherence and increases susceptibility to secondary bacterial infections.^{27,32} Bacterial pneumonias are the most common cause of mortality during influenza epidemics.

BACTERIAL PATHOGENS

Severe bacterial infections have been associated with alterations to innate immunity, such as decreased leukocyte chemotaxis and reduced reticuloendothelial function. However, these are not seen consistently and vary with the degree of bacterial invasiveness, the production of bacterial toxic products, and the host's capacity to contain the dissemination of infection. For example, *Streptococcus* sp. and *Staphylococcus* sp. produce a family of toxins called superantigens, which bind simultaneously to the T-cell receptor β chain and to class II MHC molecules, producing nonspecific activation of T cells, massive cytokine release, and eventual cell death (Fig. 38.2). Superantigens also induce T-cell anergy. Several systemic illnesses result from the superantigens' effect, including toxic shock syndrome and scarlet fever. Over 41 bacterial superantigens have been described.³³ Early antibiotic therapy can reduce the incidence of immunological disturbances due to bacterial infections.

■ IMMUNOLOGICAL DEFECTS INDUCED BY SURGERY OR TRAUMA ■

Stress induced by surgery or trauma results in a metabolic and inflammatory response to control the injury and repair the damage. Local inflammation is necessary for wound healing and defense against microbial pathogens. The reaction to injury also initiates a systemic response, with the release of several inflammatory cytokines that can affect the ability of the host to respond to immunological challenges and also predispose the patient to infection.³⁴ These responses can lead to adult respiratory syndrome (ARDS) if affecting the lungs, and to multiorgan failure, or systemic inflammatory response syndrome (SIRS). The term 'sepsis' is

Fig. 38.2 Superantigens are microbial proteins that bind nonspecific regions of MHC molecules expressed by antigen-presenting cells, and to one of over 20 subfamilies of the V β chain in the T-cell receptor. This results in activation of a large number of T cells, with release of cytokines and subsequent anergy.

CLINICAL PEARLS

- >> Surgery and severe trauma cause increased susceptibility to infections.
- >> In addition to mechanical loss of mucosal barriers, the inflammatory reaction after injury is followed by up to 10 days of anergy.
- >> Removal of dead tissue, foreign bodies and prompt restoration of enteral feeding reduce the time of increased susceptibility to infections.

reserved for SIRS of infectious etiology. The series of events leading to the inflammatory response to trauma, whether accidental or surgical, can be summarized into five steps: loss of epithelial barriers, vasodilation and increased vascular permeability, cellular activation and adhesion, and the neuroendocrine response. (Fig. 38.3)

Mechanical or chemical injury during trauma causes epithelial damage and allows access by vast quantities of microbial pathogens to the host. In addition, postoperative changes such as decreased motility of epithelial cilia can also affect the mucosal barrier. The release of inflammatory mediators in response to tissue damage and microbial products induces the next steps of vasodilation, increased permeability and cell activation. Chemotaxis of polymorphonuclear cells is decreased following acute depletion of complement proteins and the production of other acute plasma proteins. T-cell counts decrease between the second and fourth days after injury and correlate with injury severity, although they may not correlate with clinical outcome. Delayed-type hypersensitivity responses are depressed following major injury, with up to 90% of severely injured patients being anergic, as measured both by skin testing and by *in vitro* lymphocyte proliferation to mitogens and antigens. B-cell activation and antibody production are also impaired after trauma or major burns.

Stress, due to trauma or other causes, stimulates the neuroendocrine axis to produce hormones such as vasopressin, aldosterone, catecholamines and cortisol. Elevated levels of cortisol increase the release of neutrophils to peripheral blood and produce lymphopenia. In addition, the regulated secretion of prostaglandins, thromboxanes and leukotrienes is disturbed

KEY CONCEPTS

- >> Extreme environmental conditions, such as high altitude, may affect immune function.
- >> Ultraviolet light induces immune tolerance and reduces inflammation.
- >> Ionizing radiation impairs cell-mediated immunity by affecting the replication of lymphocytes.
- >> Long space flights may induce immune defects because of microgravity and space radiation, in addition to psychological stressors such as sleep cycle alterations, confinement and isolation.

and may contribute to an inefficient inflammatory response in the injured patient. Prostaglandin E₂ inhibits lymphocyte proliferation, decreases IL-2 release and inhibits NK cells up to 7–10 days after major injury.

Control of tissue damage, pain relief, nutritional support and avoidance of ischemia decrease the release of inflammatory mediators and hence reduce the immune abnormalities induced by surgical injury. Neutrophils from a well-perfused wound have better phagocytic and bactericidal activity than neutrophils from an ischemic wound.

The management of an injured patient should include prompt removal of all dead tissue to reduce the release of tissue degradation products and nonspecific immune activation. Although required in some cases immediately after severe injury, parenteral feeding leads to mucosal atrophy and an increased risk of sepsis, and should be replaced or supplemented by enteral feeding when possible.

Splenectomy

Surgical removal of the spleen is indicated following trauma or in cytopenias induced by certain medical conditions involving the excessive removal of red blood cells or platelets by the reticuloendothelial system. However, the risks and benefits of splenectomy should be carefully assessed, because it can result in barely detectable immunological changes that, nevertheless, significantly increase the risk of bacterial sepsis. Splenectomized patients are particularly susceptible to infections with encapsulated organisms such as *S. pneumonia* and *H. influenzae*. The mortality for sepsis in splenectomized patients is between 50% and 70%, emphasizing the need to avoid splenectomy when possible. Patients who are scheduled for splenectomy are recommended to receive anti-pneumococcal, anti-*H. influenzae* and anti-meningococcal immunizations at least 2 weeks prior to surgery. Revaccination after splenectomy is not efficacious. In addition, splenectomized patients should receive lifelong anti-pneumococcal antibiotic prophylaxis.

ENVIRONMENTAL CONDITIONS CAUSING IMMUNODEFICIENCY

ULTRAVIOLET (UV) LIGHT

UV light is a form of radiant energy transmitted as electromagnetic waves, with wavelengths ranging from 230 to 450 nm. It is classified as UVA if the wavelength is between 320 and 450 nm, as UVB if it is between 280 and 320 nm, and UVC if it is less than 280 nm. The most

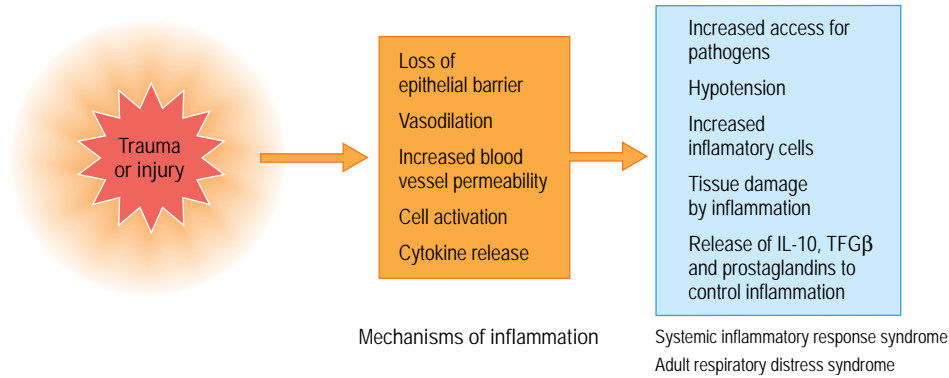

Fig. 38.3 After trauma or injury, inflammation develops to promote healing. However, massive inflammation may result in tissue damage (e.g. systemic inflammatory response syndrome – SIRS – or adult respiratory distress syndrome, ARDS). Immune regulatory mechanisms in response to inflammation may in turn induce a transient immunosuppressive state, mediated by IL-10, TGF-β and other soluble mediators.

common source of UV light affecting humans is the sun, being most intense where the atmospheric ozone layer is thinner, such as places close to the North Pole. Immunosuppression by UV light was first suspected because the incidence of malignant skin disorders increases with increased exposure to sunlight. The effects of UVB are known to be mutagenic, by creating cross-links between thymidines in DNA. The mechanisms of UV light influence on the immune system are different, as they occur even with low doses of UVB, perhaps serving to prevent an inflammatory reaction that could damage sun-exposed skin.³⁵ UV light induces the activation of NF-κB, a second-signal molecule involved in T-cell activation and apoptosis (Fig. 38.4). It also affects the activation of antigen-presenting cells, the release of cytokines, and the expression of surface markers. This UV light effect may be regulated by soluble mediators released from epidermal cells, including melanocyte-stimulating hormone, which induces hapten-specific tolerance in addition to its major role of activating melanocytes to protect the skin from sunlight. This modulation of the immune system by UV light has been used to treat autoimmune skin disorders: UVB light and psoralen plus UVA light are the treatments of choice for severe psoriasis.³⁶ The most effective wavelength of UVB is approximately 313 nm. UVA light treatment may be combined with coal tar or an occlusive ointment for increased efficacy, and remission occurs in 80% of patients.

IONIZING RADIATION

The immunosuppressive effect of ionizing radiation has been clinically evidenced by the increased susceptibility to infections and tumors in survivors of exposure to nuclear power plant accidents and atomic bomb explosions. It has also been demonstrated when used therapeutically against neoplastic diseases in humans, and experimentally in animal models. Irradiation significantly impairs cell-mediated and humoral immunity, depending on the radiation dose, the frequency of administration, rate, and temporal relationship to antigen administration. The production of lymphocytes and neutrophils, as well as other blood cell lineages, is affected according to the radiation dose causing apoptosis of hematopoietic cells in the bone marrow. All immunological components, including total, CD4 and CD8 T cells, serum immunoglobulin levels and the proliferative response to mitogens, decrease after radiotherapy. Specific

Fig. 38.4 UV light causes immunosuppression by two mechanisms: it induces apoptosis of skin lymphocytes and other immune cells by directly altering their DNA; it also activates kinases that lead to the activation of NF-κB and ultimately to cell apoptosis when other immune activation signals are missing.

immune responses are compromised primarily because of the lymphopenia. The number of macrophages can also be decreased. Phagocytosis is relatively radioresistant, whereas antigen processing by macrophages is easily impaired by low-dose radiation. Experience with the effects of ionizing radiation on the immune system demonstrates different outcomes according to applications and protocols of administration. For example, when radiation is used at therapeutic doses for myeloablation in bone marrow transplants, neutrophil counts typically recover 1 month after exposure, and lymphocyte counts recover within 3 months. Children with cancer who are treated with craniospinal irradiation have lymphopenia and impaired *in vitro* lymphoproliferative responses to mitogens for more than a year after treatment. When radiation is given in dose fractions, lymphocyte counts are reduced even more: in one experiment, when 2400 Gy were given in five fractions to children with leukemia, mean lymphocyte counts were 1840 cells/μL; when given in 12 fractions were 1120 cells/μL; and in 20 fractions were 640 cells/μL.³⁷

HIGH ALTITUDE AND CHRONIC HYPOXIA

Extreme environmental conditions, such as cold, heat or hypoxia, induce changes in the immune system, mostly associated with the response to stress. Exposure to these adverse conditions occurs during expeditions or with demanding outdoor activities, such as skiing and hiking. Acute stress temporarily increases immune function, as shown by increased mitogen proliferation. However, chronic stress causes immunosuppression, with reductions in T- and NK-cell counts, cytokine secretion and immunoglobulin levels.³⁸

Populations living at high altitude, who are affected by both high altitude and hypoxia, have more infections than people living at sea level. However, poor living conditions, minimal access to medical care and low socioeconomic levels are confounding factors that may contribute to their susceptibility to infection. There are few studies of the effect of high altitude on the immune function, and their results are equivocal. In decompression chamber studies, mitogen-induced T-cell proliferation is reduced, but T and B cells, and NK-cell activity are unchanged. Both men and mice develop good immune responses to meningococcal vaccine at an altitude of 4930 m.³⁹ Changes induced by chronic hypoxia and high altitude quickly reverse when subjects return to sea level.

SPACE FLIGHT

Long-duration space flights may become more frequent in the future, but little is known about their effects on the immune system. Immune function may be affected by stress associated with sleep cycle alterations, confinement and isolation, and other factors such as microgravity and space radiation. Increases and decreases in the numbers of total lymphocytes, both T and B cells, have been reported to occur during space flight.⁴⁰ Levels of immunoglobulins G, A and M remain stable. However, inhibition of mitogen proliferation of both human and rat T cells *in vitro*, with a reduction of IL-2 receptor expression, was observed after exposure to microgravity and rotation, possibly as a result of decreased cell-cell contact. Other abnormalities are decreased NK-cell cytotoxic activity and decreased secretion of interleukins: IL-1, IL-2, and TNF- α .⁴¹ Studies of how conditions of space travel can affect the immune system have included psychological stressors such as simulated isolation and sleep deprivation. A significant increase in plasma levels of soluble TNF- α receptor I and IL-6 were demonstrated after 4 days of total sleep deprivation. There is also evidence of reactivation of chronic latent viruses after a simulated space flight.⁴² More studies are being conducted to define the effects of space travel on the immune system.

SUMMARY

Several conditions having diverse etiologies are associated with immunological defects. These defects may have clinical consequences, mainly increased susceptibility to infections. The mechanisms of the observed immunodeficiencies are complex, involving metabolic abnormalities, such as lack of specific nutrients, and the insufficiency or excess of certain soluble factors, such as cortisol and prostaglandins. Physicians should be aware of the associations of these diseases with increased susceptibility to infection, because appropriate management of the primary disorders often can prevent and reverse the associated immune dysfunction.

Surgical stress, whether accidental or in the operating room, triggers a cascade of events to help tissue healing. However, it also releases inflammatory mediators that may result in the immune suppression of lymphocytes, monocytes and neutrophils. Secondary immunodeficiency in trauma can be reduced by minimizing tissue damage, removing unviable tissue, avoiding ischemia and providing adequate nutritional support, preferentially using the enteral route. Environmental conditions, in particular UV and ionizing radiation, have a measurable effect on the immune system that validate their consideration in the approach to the patient presenting with immunodeficiency. High altitude and chronic hypoxia and space flights have been similarly shown to affect immunologic function.

Pathogenesis of asthma

Anthony J. Frew

39

Asthma is a common clinical condition, characterized by variable airflow obstruction, occurring both spontaneously and in response to nonspecific triggers such as exercise, smoke, and fumes. Most patients have mild disease, which responds to simple bronchodilators and anti-inflammatory drugs, but a significant minority have more severe disease, with disabling levels of breathlessness, despite optimum medical management. At all levels of severity, patients may experience acute exacerbations, often in association with viral respiratory infection (Fig. 39.1).

Asthma is commoner in atopic individuals, but allergic sensitization is neither essential nor sufficient for the condition to develop. Much of what we know about the pathogenesis and pathophysiology of asthma has been derived from human and animal studies of allergic asthma, but some caution is needed in extrapolating from data obtained in these models to try to understand what is happening in nonatopic asthma. Asthma does not occur in rodents or other nonhuman animals and particular care is needed in applying data from animal models of asthma, most of which would be more accurately described as models of airways inflammation caused by allergic sensitization.

■ GENETICS ■

There is a clear familial pattern to the inheritance of asthma. Asthma, eczema, and allergic rhinitis commonly coexist within families or indeed in individuals, although not all those affected show all three clinical disorders. In many cases, there is a sequence of early-onset eczema, followed by asthma at age 3–7 years and then rhinitis during teenage years. Others develop rhinitis first, and progress later to become asthmatic. This common tendency towards eczema, rhinitis, and asthma is linked to overproduction of immunoglobulin E (IgE) antibodies, and is termed atopy. Although atopy and asthma are linked, family studies indicate that the two conditions have separate sets of genetic risk factors. Estimates of the contribution of atopy to the risk of developing asthma suggest that about 30% of the propensity to asthma is due to atopy, with considerable variation in different populations. The highest level of linkage suggests that up to 60% of asthma may be driven by atopy, while other estimates are as low as 5%.

Genome-wide searches have highlighted several distinct loci that are linked to asthma, confirming the clinical impression that this is a multifactorial disorder. Some of these genes are biologically plausible, such as polymorphisms in the FcεRI molecule on chromosome 11 or the cytokine gene cluster on chromosome 5q, while other polymorphisms are in genes that have no obvious link to asthma.¹ Interestingly, several of the genes associated with atopic eczema map to the same loci as genes predisposing for psoriasis, suggesting that it is features of the skin that may confer susceptibility for eczema. Hence by analogy it may be genes coding for structural elements of the airway or its response to injury that determine susceptibility to asthma, rather than genes encoding for the inflammatory response.

■ EPIDEMIOLOGICAL EVIDENCE ■

Asthma commonly starts in childhood or during teenage years. Wheezing in infancy does not necessarily progress to asthma in older childhood. In fact children who wheeze before the age of 3 years are no more likely to have asthma at age 6 years than those who never wheezed before the age of 3 years. Nevertheless, in some instances wheezing in infancy is followed by the later development of asthma, giving the impression that asthma started in infancy. In fact, wheezing in early childhood is generally confined to children who are born with relatively small airways. In other words, those whose airways are at the smaller end of the spectrum will tend to wheeze when they have episodes of viral bronchitis. In contrast, lung function starts off at normal levels in most children who subsequently develop asthma. Once they develop asthma their lungs will generally not develop as well as those of nonasthmatic children, so eventually asthmatic children will have reduced lung function, but that is not where they started out. Rather it is the ongoing inflammation of their asthma that leads their lungs to underdevelop.²

Allergic sensitization is an important risk factor for childhood asthma. Many children who develop asthma have had eczema in infancy, followed by allergic rhinitis, and then develop clinical asthma. This sequence is known as the allergic march, and much attention has been paid to whether it is inevitable or can be interrupted. Both on genetic grounds

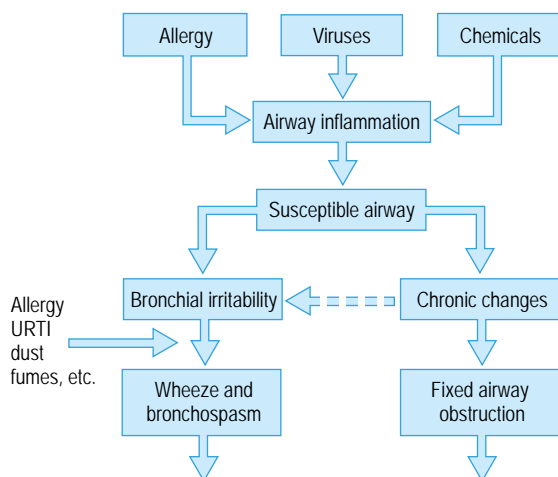

Fig. 39.1 The role of allergy and other factors in causing airways inflammation, bronchial irritability, wheeze, and fixed airways obstruction. URTI, upper respiratory tract infection.

and in careful studies of birth cohorts it seems that the tendency to have eczema, rhinitis, and allergic sensitization (the so-called atopic phenotype) is inherited differently from the tendency for asthma. But in those who are atopic, asthma will show up in childhood if they also possess the genetic predisposition to asthma, whereas in those who are nonatopic, asthma is unlikely to appear in childhood, but may surface as a problem in adulthood.

Survey evidence from across the developed world has shown a clear increase in rates of asthma during the second half of the 20th century. Looking back, it seems that this rise may have started in the USA during the 1930s, while in Europe it started later – probably in the 1950s in the UK, in the 1960s in West Germany, and in the 1990s in the former socialist republics of Eastern Europe. In all cases it seems that the rise in asthma and in allergic sensitization parallels improvements in living conditions, although the precise feature of prosperity that drives these trends is not yet known. Indeed, it may well be different in different countries, due to interactions between diet, genetics, and the environment. In searching for an explanation of these secular trends, it is clear that it cannot be a simple genetic change: the timescale is too short for there to have been a sudden change in the gene pool. Equally, the risk of asthma and allergy is not evenly distributed through the population since some families are at much greater risk than others. It therefore seems likely that the change is due to one or more environmental changes operating on a genetically predisposed subset of the population.

Possible environmental factors include allergies, housing, air pollution, diet, and various aspects of infection. We sometimes forget how much our housing and daily lives have changed in the past 50 years. For example, houses are now much better heated and insulated – in the UK in the 1950s, central heating was unusual, and wall-to-wall carpeting unheard of. Partly as a result we now wear different clothes and wash them much more frequently. We also take more baths and showers, resulting in considerably more humidity inside our houses, and we have radically changed our bedding, with duvets replacing traditional blankets and quilts. Many of these changes have made our homes much

KEY CONCEPTS

POSSIBLE ENVIRONMENTAL FACTORS RESPONSIBLE FOR THE RISE IN ASTHMA

- >> Allergic sensitization
- >> Factors promoting allergen exposure (especially to house dust mite)
 - >> Housing design
 - >> Increased humidity
 - >> Carpets/rugs
 - >> Bedding
 - >> Air pollution
 - >> Motor vehicles
 - >> Ozone
 - >> Particulate matter (especially diesel exhaust)
- >> Diet
 - >> New foods
 - >> Food processing
- >> Infections
 - >> Respiratory viruses
 - >> Environmental bacteria
 - >> Gut microflora

more favorable for house dust mites, and there is circumstantial evidence that exposure to house dust mite allergens is now much higher than it was in the past.

Diets have changed too – we now have year-round access to fruits and vegetables that used to be seasonal; food is picked unripe, processed, and transported halfway round the world, and all this requires new technology to make sure the fruit is ready to eat when it reaches our shelves. Artificial ripening of fruits changes their chemical composition and may alter their allergenicity. We also expect our food to be beautiful and clean, so we reject anything that is flawed or dirty. All these factors have altered what we eat and our exposure to environmental bacteria. This shows up in changes in the gut bacterial flora, which is known to be a major influence on the development of the immune system. Analysis of gut bacteria over the past 40 years in developed countries indicates that we now have a much narrower range of gut bacteria compared to 40 years ago, and that the development of allergy in childhood is associated with having a more restricted gut flora.³

It is clear that more people are sensitized to common airborne allergens than was the case 40 years ago. However, while allergic sensitization is a risk factor for asthma, data from Australia suggest that rates of asthma doubled during the 1980s, without any concurrent change in the rate of allergic sensitization to common allergens such as house dust mite or grass pollen.⁴ This indicates that what changed in the 1980s may not have been allergy itself, but the likelihood that allergy would be translated into disease.

KEY CONCEPTS

HOW MAY POLLUTANTS AFFECT ALLERGY AND ASTHMA?

- >> Promotion of immunoglobulin E (IgE) synthesis
- >> Oxidative stress
 - >> Direct – from redox-active metal ions on particulate matter
 - >> Indirect – through recruitment and activation of inflammatory cells
- >> Particulate matter acting as a vector for allergenic molecules
- >> Promotion of allergic inflammation
- >> Enhancement of effector cell function
 - >> Releasability of basophil mediators
- >> Damage to structural elements of airway
 - >> Ciliary function
 - >> Epithelial integrity
 - >> Smooth muscle

AIR POLLUTION AND ASTHMA

Air pollution has been blamed for many modern ills. It is unlikely that air pollution is good for us, but more difficult to say how bad it is. In general, air quality today is much better than in the 1950s. This reflects clean-air legislation designed to reduce the emissions from coal-burning power stations and factories. Indeed, levels of black smoke and sulfur dioxide have fallen progressively over the past 50 years, so they can hardly be blamed for the rise in allergy and asthma. The only pollutants that have increased in recent years are ozone, nitrogen oxides, and particulates, all of which are largely related to the meteoric rise in vehicular traffic during the late 20th century.

Pollutants could influence asthma in several different ways. Firstly, the organic chemicals associated with diesel exhaust particles have been shown in humans and in animal studies to enhance IgE production to newly encountered allergens.⁵ Second, particulate matter (PM) can carry allergenic molecules down into the airways where they may be taken up by antigen-presenting cells and, by being presented together to immunocompetent cells, the consequent immune response may be deviated towards an allergic pattern. Moreover, in sensitized individuals, this vector function of PM allows allergen to reach sites that might otherwise have been inaccessible and trigger allergic reactions. Third, both ozone and particulate pollutants impose an oxidant stress on the airways, adding to the oxidant stress that is already present in asthma due to ongoing airways inflammation. This happens both as a direct result of oxidation by ozone and PM, and as an indirect result, through the recruitment of neutrophils to the airway. The organic chemicals on diesel exhaust particles increase the releasability of histamine and interleukin-4 (IL-4) from basophils,⁶ and have adverse effects on the structural elements of the airway, including mucus release and ciliary function.⁷ While some of these effects can only be shown in animal models after high-dose exposure, there is good epidemiological evidence

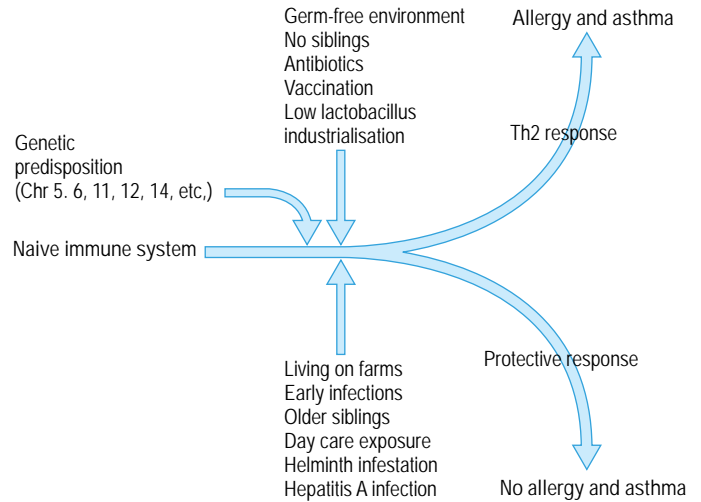

Fig. 39.2 Factors implicated in the hygiene hypothesis.

that small increases in ambient ozone concentrations or PM levels are associated with decrements in lung function and increased rates of admission to hospital with asthma.^{8,9}

INFECTIONS AND ASTHMA

Population surveys have shown that first-born children are more likely to develop rhinitis and asthma than those with older siblings. Interestingly, this excess risk does not apply to first-born or only children who go to day care at an early age. The general consensus is that increased exposure to respiratory viral infections is protective against the development of allergy and asthma. It is noteworthy that early use of day care does not protect against eczema. This suggests at the very least that asthma and eczema have distinct risk profiles; however they may be linked in the atopic march.

Once asthma is established, viral infections are a common trigger of symptoms.¹⁰ This is partly because minor changes in airflow caliber may become manifest as asthmatic symptoms, and partly because viral infections appear to exacerbate the pattern of airways inflammation associated with asthma. Other forms of infection appear to protect against asthma. This concept has been entitled the “hygiene hypothesis” to explain the rise in asthma. Several strands of evidence indicate that early exposure to infection may lead to deviation of the immune response to allergens that are encountered subsequently or concurrently (Fig. 39.2). So, for example, surveys of Italian army recruits show that exposure to hepatitis A in childhood is associated with a reduced risk of asthma at age 18. This reduction in risk is not thought to be a direct effect of hepatitis A, but rather to reflect exposure to contaminated water supplies, a common problem in southern Italy. Recruits with serological evidence of other infections, not transmitted by the feco-oral route, show no protection against asthma.¹¹

Other evidence of the protective effect of infections comes from studies of children raised in farming communities in the Bavarian and Swiss Alps. In these traditional communities, people live in close proximity to cows, and often take their infants to the cow barn when they are milking the cows. Children who are taken into the cow barn or who drink

unpasteurized milk before the age of 1 year have a substantially reduced risk of developing allergies. These effects are additive, but there is no protection if the child is only exposed after the age of 1 year.¹² Taken together these studies indicate that early exposure to infectious agents plays an important role in defining our immune responses, and that the window of opportunity to influence this may be very early in life.

A variety of animal models have been used to examine the mechanisms that may underpin these epidemiological observations. Stimulation of Toll-like receptor 9 (TLR-9) by unmethylated bacterial DNA biases the immune response towards a Th1 pattern and can be shown to reduce the tendency of mice to make IgE responses to ovalbumin. Similarly, infestation with parasitic worms can reduce the ability of mice to become sensitized (in terms of IgE) and attenuates the airways response to allergen exposure. Instead, there is an increase in allergen-specific IgG₄, consistent with an IL-10-dominated T-cell response. This effect operates both in naïve animals and in those that have already been sensitized, suggesting it may be a viable approach for use in patients with established allergic asthma. However, the precise nature of what needs to be done to translate these observations into practical ways to prevent asthma remains unclear.

ALLERGEN CHALLENGE

Much of our understanding of the pathophysiology of asthma is derived from studies of the response to inhaled allergen. In sensitized subjects, inhalation of relevant allergens leads to various different patterns of bronchoconstriction. Within 10–15 minutes of allergen inhalation, most sensitized subjects start to show an immediate or early asthmatic response (EAR). This peaks after about 30–60 minutes, after which spirometric measures generally return towards baseline. A further period of bronchoconstriction may start 3–4 hours after the initial challenge. This late-phase response occurs in about 50% of those who show an early-phase response. The late asthmatic response (LAR) may be more profound than the initial response, and generally lasts longer, peaking 6–8 hours after inhalation, and continuing for up to 24 hours (Fig. 39.3). Subjects who have shown an LAR will usually show increased nonspecific bronchial reactivity (NSBR) for several days to 2 weeks afterwards, even though their spirometry has returned to baseline.¹³ Clinically this may be evident as nocturnal cough, spontaneous wheeze, and bronchial irritability on exposure to nonspecific irritants such as solvents, paint, perfume, and newsprint. Isolated late-phase reactions are rarely seen after inhalation of ordinary airborne allergens, but are sometimes observed after inhalation of low-molecular-weight sensitizers such as di-isocyanates and other chemicals that cause occupational asthma.

The mechanisms of the EAR and LAR have been studied in detail, both in humans and in animal models. The principal events of the EAR are the activation and degranulation of mast cells, and subsequent constriction of bronchial smooth muscle by mast cell mediators. Histamine and leukotrienes can be demonstrated in the airways within 10–15 minutes of challenge, while pretreatment with antihistamines blunts but does not abolish the EAR. Histamine probably contributes about 25% of the EAR, as judged by the area under the forced expiratory volume in 1 second (FEV₁)–time curve. By combining a variety of drugs, it is possible to attenuate the EAR, demonstrating that a combination of histamine, prostaglandins, and leukotrienes account for most of the early-phase bronchoconstriction.¹⁴

Fig. 39.3 Timecourse of isolated early reaction and late-phase reaction after allergen inhalation. Subjects are challenged with sufficient allergen to induce a 20% early fall in forced expiratory volume in 1 second (FEV₁) and are then followed to see whether a late reaction occurs.

In contrast, most of the acute bronchoconstriction seen after exercise seems to be mediated through leukotrienes. During the EAR, endothelial adhesion molecules are upregulated on the small blood vessels of the airway, and a variety of inflammatory leukocytes start to accumulate, but they are not thought to play any real part in triggering the contraction of bronchial smooth muscle that causes the physiological changes of the EAR. During the LAR, neutrophils, eosinophils, and T lymphocytes are drawn into the tissue and migrate into the airways. Edema of the airways mucosa develops, and mucus is secreted into the airway. During the LAR, the airway T cells express Th2-type cytokines, probably reflecting an influx of cells with Th2 phenotype rather than a deviation of the resident lymphocytes. Conceptually it is easy to see how this influx of T cells producing IL-4, IL-5, and IL-9 would enhance an ongoing pattern of allergic inflammation, with consequent accumulation of eosinophils and enhancement of allergen-specific IgE. Smooth-muscle contraction plays a part in the LAR, with leukotrienes released from eosinophils playing a particularly important role. However, the bulk of the airflow limitation is caused by mucosal inflammation, which narrows the airway lumen, and has a disproportionate effect on airflow when the airways' smooth muscle contracts (Fig. 39.4).

The LAR can be prevented by pretreatment with inhaled corticosteroids, or leukotriene antagonists, but is not affected by pretreatment with short-acting beta-adrenergic agonists or antihistamines. This pattern of pharmacological response, together with the development of NSBR after the LAR, but not after the EAR, has led investigators to conclude that the LAR is a better model of real-life asthma than the EAR. However, it is still a model and does not reproduce all aspects of asthma, so while drugs which work in the LAR are promising candidates, they may not necessarily work in chronic asthma. Equally, we may find drugs that fail to block the LAR, but are useful for more chronic features of the disorder (see section on remodeling, below).

Fig. 39.4 Effect of airways inflammation, mucosal edema, and intraluminal mucus on the caliber of airways subjected to nonspecific constriction.

AIRWAYS INFLAMMATION

Until quite recently asthma was regarded as a disorder of smooth-muscle function, but in the 1980s fiberoptic bronchoscopy revealed that mucosal inflammation was present in even the mildest cases of asthma. In most subjects with mild asthma, who are not taking any regular therapy, increased numbers of mast cells and eosinophils are present in the bronchial mucosa. Following treatment with inhaled corticosteroids, both cell types are reduced, with eosinophils being particularly sensitive to steroids. These reductions in airway inflammation are associated with improvements in asthma symptoms, NSBR, and other measures of lung function. However, some subjects with asthma show few eosinophils, and it remains unclear whether these patients are at one end of a spectrum or whether they represent a different pathology, which also expresses itself clinically as asthma. In patients with more severe disease, significant numbers of eosinophils may persist in sputum or the airways mucosa despite taking long-term inhaled steroids.¹⁵ Some have argued that this is why the patients fail to improve despite therapy; others conclude that the eosinophil may be less important in causing the disease in those with more established disease.

The pattern of airways inflammation in asthma is controlled by cytokines of the Th2 cluster (Chapter 10). These include IL-4 and IL-13 which regulate IgE production, IL-5, which is heavily implicated in eosinophilia, and the counterregulatory cytokines IL-10 and transforming growth factor- β (TGF- β), which suppress T-cell function but activate other cells that contribute to the remodeling of airways (see below). T-lymphocyte activation is observed in airway biopsies from asthmatic patients, although T-cell numbers may not be increased compared to healthy control subjects.¹⁶ The cytokine profile of mucosal T cells differs from those retrievable from the airway lumen by bronchoalveolar lavage (BAL). In particular, luminal T cells show activation markers such as

CLINICAL PEARLS

FEATURES OF THE LATE ASTHMATIC REACTION

- >> Onset 2–3 hours after challenge; peak 8–12 hours; lasts up to 24 hours
- >> Occurs in about 50% of subjects after an allergen inhalation that causes an early fall in forced expiratory volume in 1 second (FEV₁) of about 20%
- >> Leukotriene release causes prolonged bronchoconstriction
- >> Infiltration with eosinophils, T cells, and neutrophils
- >> Followed by increased nonspecific bronchial hyperreactivity for up to 3 weeks
- >> Blocked by pretreatment with steroids, but not by antihistamines or short-acting beta-adrenergic agonists

CD25 and human leukocyte antigen (HLA)-DR, and produce interferon- γ (IFN- γ) upon stimulation, while those from the mucosa show more of a Th2 phenotype, with expression of IL-3, IL-4, and IL-5.^{17, 18}

The implications of expressing CD25 are unclear, since CD25 is expressed both on activated T cells and on anergic T cells. Flow cytometric analysis suggests that most CD25+ cells in BAL from asthmatic patients are unresponsive to mitogenic stimulation. It remains unclear whether the T cells are the prime movers in airways inflammation or whether they are recruited in response to injury. Conventionally, T cells should respond to the antigens they recognize and not to other stimuli, in which case one would have to argue either for a dense concentration of antigen-specific cells or a broad range of antigenic targets in the airway. It is perhaps more likely that some of them serve to amplify the response to allergens. Given that T-cell activation is even more prominent in the airways of patients with nonallergic asthma (also called intrinsic asthma), there are interesting and unresolved questions to answer about the nature of the antigen (if any) that is involved.

Mast cells have also been identified as a source of cytokines including IL-4 and IL-5, the key Th2 cytokines that respectively regulate IgE production and eosinophil differentiation.¹⁹ Mast cells are found in increased numbers in asthmatic airways, and can be activated by allergen inhalation, releasing histamine and leukotrienes, which cause acute bronchoconstriction. While antihistamines can block the effects of allergen inhalation, these drugs show little benefit in clinical asthma, suggesting that histamine is not an important mediator except perhaps in acute bronchospasm induced by heavy allergen exposure, e.g., those who wheeze on acute exposure to cats. In contrast, leukotriene antagonists are clinically effective, especially against exercise-induced symptoms, confirming that leukotrienes are relevant mediators of asthma.

However, the heterogeneity of response to leukotriene antagonists suggests that the importance of leukotrienes varies between patients. Moreover there are other sources of leukotrienes, especially eosinophils, so the activity of leukotriene receptor antagonists (LTRAs) in asthma does not of itself prove the relevance of mast cells. Other mast cell products that may affect asthma include the granule proteases, of which tryptase is the best studied. Intuitively it seems more likely that tryptase would be involved in airway remodeling rather than acute inflammation, although a tryptase antagonist has been shown to attenuate the allergen-induced late-phase

asthmatic reaction in humans.²⁰ This suggests that tryptase may cleave and release proinflammatory chemokines from the intercellular matrix.

For many years the eosinophil has been considered a hallmark of asthma. It is certainly true that many asthmatics have eosinophils in their airways, and sometimes they may be increased in blood as well, although at any given time the vast majority of eosinophils are located in tissue rather than circulating. Eosinophils are recruited to the airways during asthma exacerbations and following allergen inhalation, when their numbers peak around the time of the LAR. Conversely, they are reduced by treatment with inhaled or systemic steroids.

In intrinsic asthma there are even more eosinophils in the airways than in allergic asthma, but their numbers are more difficult to reduce with steroid therapy. Relevant eosinophil products include the basic granule proteins (major basic protein, eosinophil cationic protein, eosinophil-derived neurotoxin, and eosinophil protein X), which can damage airways epithelium at concentrations achieved in sputum from asthmatic patients. Cysteinyl leukotrienes are also produced in large amounts by eosinophils and this seems the most likely mechanism by which they cause late-phase bronchospasm.

However there are some cautionary notes regarding the role of eosinophils in asthma. Firstly, there is no correlation between sputum eosinophilia and bronchial hyperresponsiveness (BHR). BHR is a key feature of asthma and if the eosinophil were truly critical to the pathogenesis of asthma, one might expect some degree of linkage between the degree of BHR and the number of eosinophils in sputum. Secondly, in recent studies with monoclonal anti-IL-5 antibodies it proved possible to eliminate eosinophils from the blood and sputum without materially affecting the ability of allergen to induce NSBR.²¹ Moreover, treatment with anti-IL-5 monoclonal antibody seems to have no detectable effect on clinical asthma.

Alternative approaches to suppressing eosinophils include the use of chemokine antagonists, since eosinophils selectively express the CCR3 receptor, which recognizes the eotaxin family of chemokines. Eotaxin is present in increased amounts in asthma and may contribute to the increased numbers of eosinophils found in asthmatic airways. Early clinical trials with CCR3 antagonists have not yet demonstrated a clear role for CCR3 in asthma. This may be because the antagonists are inefficient, because there is biological redundancy, or of course because the eosinophil is not really important.

Interest in the neutrophil as a possible player in asthma has been rekindled lately, following the recognition of airways neutrophilia in some patients whose asthma is "difficult to control." In the absence of any specific antagonists for neutrophils and their products, it has been difficult to assess their true contribution to the clinical condition. However, asthma is definitely associated with a local oxidative stress to the airway, and neutrophils contribute to this, through their oxidative burst – the principal means by which they kill bacteria. Reactive oxygen species (ROS) cause lipid peroxidation that can be detected in BAL and serves as a direct measure of oxidative stress.²² Low levels of ROS signal via the transcription factor Nrf2 to induce enzymes that upregulate antioxidant defenses – principally through the synthesis of glutathione. Polymorphisms in these enzymes are associated with marked variation in the risk of asthma, suggesting that failure to detoxify ROS is a permissive factor for asthma.²³ If the antioxidant defenses are overwhelmed, MAP kinase and NF- κ B pathways are activated, leading to synthesis of a wide range of

KEY CONCEPTS

POSSIBLE CAUSES OF OXIDATIVE STRESS IN ASTHMA

- >> Inflammation
- >> Ozone
- >> Particulate matter
- >> Smoke (including tobacco)
- >> Pollutant gases (SO₂, NO₂ etc.)
- >> Chemicals (including isocyanates)

proinflammatory cytokines and chemokines, including many that have been implicated in asthma and airways inflammation. Extreme levels of oxidant stress will lead to cellular apoptosis. Although it is unclear whether this is important in clinical asthma, it is easier to induce apoptosis via oxidant stress in epithelial cells cultured from asthmatic airways as compared to epithelial cells from nonasthmatic airways.²⁴

COMPARISONS WITH ALLERGIC RHINITIS

Some useful insight into the specificity of allergic inflammation in asthma can be obtained by comparing the histology of asthma with that of the lower airways of patients with allergic rhinitis who have normal bronchial reactivity and no clinical features to suggest asthma.²⁵ In such subjects, submucosal eosinophilic infiltration and increased numbers of epithelial mast cells are seen, at a level intermediate between that found in asthmatic subjects and healthy controls. Expression of mRNA for tumor necrosis factor- α (TNF- α) is also found in the biopsies from both asthmatic and rhinitic subjects. Eosinophil activation occurs in both groups. Taken together this adds to the doubts raised above concerning the role of eosinophils in causing asthma.

Although mast cell numbers are increased in both asthma and rhinitis, there is evidence that mast cells in asthmatics show more signs of degranulation than those in atopic controls, suggesting that it is a difference in mast cell activation status rather than in mast cell numbers that may lead to BHR.²⁶ IL-1 β and TNF- α are both proinflammatory cytokines that can contribute to initiation and perpetuation of the inflammatory response with endothelial activation, increased adhesion molecule expression, and subsequent inflammatory cell recruitment. mRNA levels of both these cytokines were increased in both the rhinitics and asthmatics compared to normal controls, with no difference between these two atopic groups. The increased expression of these cytokines found in asthma may therefore be a feature of atopy rather than asthma. Looking for differences between rhinitis and asthma, there were increased numbers of CD8 T cells and relatively increased expression of mRNA for IFN- γ in the biopsies from the rhinitic group, suggesting that in a subject who is atopic these changes might be protective against asthma.

KEY CONCEPTS

FEATURES OF AIRWAYS REMODELING

- >> Epithelial damage
- >> Subbasement membrane collagen deposition
- >> Mucous gland hyperplasia
- >> Airways smooth muscle
 - >> Hypertrophy
 - >> Increased contractility
 - >> Decreased relaxation
- >> Altered epithelial function
- >> Altered intercellular matrix

REMODELING

Inflammation clearly plays an important part in the initiation of asthma, and in exacerbations of the condition, but the long-term consequence of these processes is a permanent change in the structure and function of the airway. In a broad sense, the airway is 'remodeled' so that it behaves differently when the patient is exposed to nonspecific agents such as cold air, exercise, smoke, perfume, and vehicle exhaust. The net result is that asthmatic patients have irritable airways, and that once these are constricted, the airways may remain narrowed for longer than would occur in nonasthmatic people.

There are several histological and physiological features of remodeling which occur to varying degrees in each individual with asthma. Histologically, the most obvious feature is thickening of the basement membrane, which is present in all asthmatics regardless of disease severity. When assessed by electron microscopy, the apparent thickening is due to deposition of collagen beneath the true basement membrane. Immunostaining shows that this is type III collagen, a variant associated with wound repair processes. This is produced by myofibroblasts (fibroblasts that have some ultrastructural features of smooth-muscle cells) that differentiate in the submucosa and migrate into the subbasement membrane zone. These cells are thought to be induced and regulated by growth factors released from the epithelium (see below). In addition, several regulatory cytokines produced by T cells and eosinophils have profibrotic effects. These include TGF- β , IL-10, and IL-17, all of which can be demonstrated in increased amounts in human asthmatic airways, and promote fibrosis, while at the same time downregulating T-cell and B-cell function.²⁷

Asthmatic airways constrict more vigorously than normal nonasthmatic airways. There is an increased amount of muscle (hypertrophy) but the muscle is also altered in function. Muscle from asthmatic airways shortens more than normal muscle and generates more force *in vitro*. Moreover, once contracted, it is more difficult to relax than normal airways smooth muscle.²⁸ Pretreatment of smooth muscle with the proallergic cytokine IL-13 decreases its responsiveness to the β_2 -agonist isoproterenol, demonstrating that proallergic cytokines may have pleiotropic actions, contributing both to the induction of IgE and to the remodeling process.²⁹

The airways epithelium is thought to play a major role in airways remodeling. In the past, the airways epithelium was often considered as an innocent victim of the asthmatic process, becoming damaged and shed when eosinophils and other inflammatory cells released their toxic products. However, more recently it has been appreciated that growth factors and chemokines released from the epithelium play an active part in remodeling. Several chemokines, including IL-8, are present in the epithelium, where they are bound to the extracellular matrix (Chapter 11). When inflammation occurs, there is release of matrix metalloproteases which liberate and activate these chemokines, which in turn can attract neutrophils and other inflammatory cells to the area of injury. Epidermal growth factors that can induce structural alterations in the airways are also released, including many of the changes associated with airways remodeling.³⁰

Recent genetic analysis has revealed a link between asthma severity and a metalloprotease (ADAM33), which is increased in patients with mild and moderately severe asthma compared to healthy controls.³¹ Polymorphisms in ADAM33 have also been linked to asthma.³² Fibronectin and collagen from the extracellular matrix may also participate in remodeling. For example, it is known that airways smooth-muscle cells from asthmatic airways produce more eotaxin than those nonasthmatic subjects. This eotaxin release is enhanced by coculture with fibronectin and type I collagen, suggesting that these extracellular matrix components are responsible for the upregulation of smooth-muscle function.³³

Several models of airways remodeling have been developed, and there is considerable argument about how relevant these are to real-life asthma. However, both in animals and in humans, it seems that corticosteroids have little effect on the histological or physiological correlates of remodeling. This goes some way to explain why corticosteroids can damp down airways inflammation but do not abolish all symptoms. In contrast, leukotriene antagonists can reverse some features of remodeling, including airways smooth-muscle mass and subepithelial fibrosis, in animal models that are resistant to steroids.³⁴ Several key aspects of the remodeling process remain unclear: current research lines are attempting to work out why some exposures lead to sensitization as opposed to tolerance, why not all those who are sensitized become symptomatic, and what determines whether the responses to downstream stimuli are limited or lead on to disease progression, airway remodeling, and chronic symptomatology (Fig. 39.5).

STEROID-RESISTANT ASTHMA

A small minority of asthmatic patients are resistant to the beneficial effects of steroids. In all other respects they have asthma, i.e., their airways obstruction is variable and their failure to respond to steroids is not because they have chronic obstructive pulmonary disease (COPD) that has been misdiagnosed. Even when given large doses of oral steroids, these patients' lung function does not improve.³⁵ Clinically they develop the usual steroid side effects, indicating that they have receptors for steroids. The molecular and cellular basis of steroid resistance remains uncertain. Clinical investigations have shown that steroid insensitivity in these patients is associated with loss of nuclear translocation of the alpha form of the glucocorticoid receptor.³⁶ Some patients who have clinically severe asthma despite

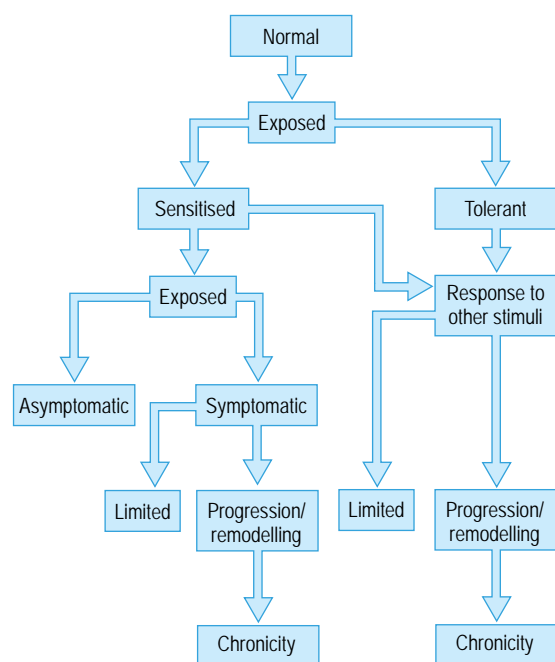

Fig. 39.5 Key decision points in the biology that leads to chronic asthma.

taking oral and high-dose inhaled steroids show persistent airways neutrophilia and increased expression of TNF- α mRNA and protein.³⁷ While this suggests a possible role for TNF- α in severe asthma, clinical trials of TNF- α antagonists have not yet confirmed whether this is a critical element in steroid-resistant asthma.³⁸

NEURAL MECHANISMS

The airways are supplied by both parasympathetic and sympathetic autonomic nerves. Vagal tone tends to constrict the airway, while sympathetic activity relaxes it. There is little evidence of parasympathetic overactivity in asthma, although anticholinergic agents such as ipratropium, oxitropium, and tiotropium do have a role in opening up the airways during acute exacerbations. Sympathomimetics such as salbutamol/albuterol are useful bronchodilators in all grades of asthma, but again there is no real evidence that sympathetic underactivity or insensitivity to epinephrine plays any part in the pathogenesis of asthma. In contrast, there is evidence that the nonadrenergic, noncholinergic nerves are implicated in asthma. Specifically, substance P is depleted in the airways of patients with mild asthma and this effect is also seen in normal human airways after exposure to ozone.³⁹ Another way that neuronal mechanisms could be involved is via neurotrophins. Nerve growth factor, brain-derived neurotrophin factor (BDNF) and neurotrophin-3 have all been detected in increased amounts in airways lavage 8 hours after local allergen challenge in humans. Among other actions, BDNF has been shown to increase eosinophil survival in the airways – endobronchial eosinophils have receptors for BDNF whereas those in the peripheral blood do not.

ANGIOGENESIS

In established asthma there are increased number of blood vessels in the submucosa of medium and small airways, which may contribute to their altered physiology, including the response to exercise.⁴⁰ It has been postulated that angiogenic factors such as vascular endothelial growth factor (VEGF) may play a role in this process, and increased levels of VEGF can be detected in mild to moderate asthma.⁴¹ VEGF is upregulated by hypoxia and a variety of growth factors and proinflammatory cytokines, including epidermal growth factor, TGF- β , IL-1 α , and IL-6. However, VEGF expression is downregulated by other cytokines implicated in asthma such as IL-10 and IL-13. The subepithelial hypervascularity and airways angiogenesis found in asthma are partially responsive to inhaled steroids, although VEGF concentrations in BAL do not fall after steroids.

ASTHMA AND CHRONIC OBSTRUCTIVE PULMONARY DISEASE

In older patients there is often a degree of uncertainty about whether they have true asthma or some form of COPD. There is no doubt that people can develop asthma in adulthood, with all the usual features of variable airflow obstruction and reversibility to standard therapies. On the other hand many people with definite COPD have a degree of variability in their airflow obstruction. We tend to use the same drugs to treat both conditions, so confusion can easily arise in the minds of both patients and doctors about the true nature of the condition that the patient has. However, the functional deficit in exacerbations of asthma is quite different from that observed in COPD.

Typically in COPD, a significant proportion of the lung consists of space that is ventilated but not perfused. This means that ventilation is inefficient and it is difficult to compensate for hypoxia by increasing ventilation since the bulk of increased effort is spent in ventilating lung units that are not receiving blood. In contrast, during asthma exacerbations, areas of the lung become plugged and cease to be ventilated. Air is trapped in these areas, although over time the air is resorbed and the lung unit collapses. Meanwhile, blood continues to pass through the unventilated area, with the result that unoxygenated blood returns in the pulmonary veins, and the arterial oxygen saturation falls. Increasing the ventilation of the working areas of the lung cannot compensate for this shunting of venous blood through unventilated areas so the patient remains hypoxic.

In the past, there was a lively debate about whether patients with asthma would go on to develop COPD in later life. This was known as the 'Dutch hypothesis' for COPD, which contrasted with the British and American view that COPD resulted mainly from cigarette smoking, air pollution, and conditions that increased oxidative stress and protease activity. While both asthma and COPD show evidence of airflow limitation, we now know that the pathological basis of this is quite different. In asthma, increased airways resistance is due to inflammation and remodeling of the airway wall while the substance of the peripheral lung is normal. In COPD, the main cause of airflow limitation is premature collapse of small and medium-sized airways due to loss of elastic recoil.

CLINICAL PEARLS

ASTHMA AND CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD)

Common features

- >> Airflow obstruction
- >> Shift of tidal breathing towards total lung capacity during exacerbations

Asthma-specific features

- >> Reversibility
- >> Airways inflammation (predominantly eosinophilic)
- >> Th2-cytokine pattern
- >> Reduced elastic recoil due to edema
- >> Perfusion of underventilated areas (especially during exacerbations)

COPD-specific features

- >> Irreversible airflow obstruction (predominantly)
- >> Destruction of alveoli
- >> Reduced elastic recoil due to loss of lung tissue
- >> Ventilation of underperfused areas
- >> Response to anticholinergic agents

There may be some inflammation of the airway wall, but this does not seem to have direct consequences on airways physiology. Excess mucus production can be a feature of both conditions. In asthma the mucus is often viscid and causes plugging of small and medium-sized airways during exacerbations, whereas in COPD patients with chronic bronchitis, mucus hyperplasia in large airways causes excess sputum production, but has little effect on airflow resistance or gas exchange.

Management of the asthmatic patient

Susana Marinho, Adnan Custovic

40

Asthma is a complex multifactorial disorder involving a variety of different mechanisms, in which genetic and environmental influences play intertwining roles, resulting in heterogeneous clinical phenotypes. The key role played by chronic inflammation in the pathology of asthma has implications for its diagnosis, prevention and management.

Asthma is one of the most common chronic conditions worldwide.¹ International studies have demonstrated striking geographical variations in the prevalence of asthma throughout the world, the highest being observed in English-speaking countries and Latin America, and the lowest in the Mediterranean, Eastern Europe and rural areas of Africa and China. In addition, there is considerable evidence documenting a worldwide increase in the prevalence of asthma and other allergic diseases over recent decades.¹ It remains to be seen whether this trend is ongoing, as there are recent reports suggesting that in some areas it might have reached a plateau or reversed.

■ DIAGNOSIS ■

Owing to the complexity and multiplicity of asthma phenotypes, there is no single measure or procedure that allows a clear-cut confirmation or exclusion of the diagnosis. Diagnosis is based on a history of episodic respiratory symptoms consistent with airflow obstruction, combined with physical findings, objective measurements of airway obstruction, and reversibility (and exclusion of other conditions with similar clinical presentation).

■ HISTORY AND PHYSICAL EXAMINATION ■

The medical history should focus on the type and pattern of symptoms, precipitating and/or exacerbating factors, course of the disease and response to treatment, and family and social history. The key manifestations of asthma are a variable combination of wheezing, shortness of breath, chest tightness, cough and sputum production. The pattern of symptoms and course of the illness vary between patients: it is characteristically intermittent, but ranges from mild

episodic symptoms that remit spontaneously to severe and sometimes fatal exacerbations, or persistent and progressive symptoms leading to significant disability.¹ Symptoms are typically triggered/exacerbated by viral respiratory infections, exercise, indoor and outdoor pollutants and irritants, allergens, medications, food additives and preservatives, emotions and endocrine factors.¹ Asthma symptoms follow a circadian rhythm and are often worse at night, which can lead to disturbed sleep and daytime fatigue; the frequency of nocturnal episodes is one of the indicators of disease severity.¹ Because the symptoms are variable, physical examination of the chest may be normal. Wheezing is the most typical finding, but may be absent in some symptomatic patients and during severe asthma exacerbations (when other physical signs of respiratory distress are obvious). Other signs may also be observed during symptomatic periods (e.g., tachypnea, tachycardia, chest hyperinflation, use of accessory muscles with intercostal recession, hyperresonant percussion note, prolongation of expiration). Other allergic diseases (rhinitis, conjunctivitis and eczema) may also be observed.

■ FUNCTIONAL ASSESSMENT ■

Lung function measurements are useful in establishing the diagnosis, assessing its severity and monitoring responses to treatment. Peak expiratory flow rate (PEFR) variability is a useful test, especially in the community. Diurnal PEFR variation > 20% is considered diagnostic; it may also be used to assess asthma severity, which is broadly proportional to the magnitude of the variability. However, in mild intermittent asthma or in severe intractable disease this variability may not be present.

For patients with a history suggesting asthma but having normal lung function, measurement of airway responsiveness to methacholine, histamine or exercise may facilitate the diagnosis.¹ These methods (with the exception of exercise challenge) are sensitive but relatively nonspecific, as airway hyperresponsiveness is also found in patients with allergic rhinitis or airflow limitation due to cystic fibrosis, bronchiectasis, chronic obstructive pulmonary disease (COPD), etc.

Fig. 40.1 Alteration of flow-volume loops in asthma. Six characteristic spirometric patterns of lung disease are shown. Expiratory and inspiratory flow is plotted against forced vital capacity (FVC). The expected curve is represented by the dashed line. (Adapted from Ruppel GL. Manual of pulmonary function testing, 7th edn. St Louis: Mosby, 1998, with permission from Elsevier.)

SPIROMETRY

Demonstrating reversibility of airflow limitation after bronchodilator inhalation supports a diagnosis of asthma. The forced expiratory volume in 1 second (FEV_1), forced vital capacity (FVC), and mid-expiratory flow rates obtained from flow-volume loops provide accurate and reproducible (albeit effort-dependent) information (Fig. 40.1). Characteristically, in airflow obstruction there is a decrease of both volumes and flows but FEV_1 is decreased more than FVC, resulting in a decreased FEV_1/FVC ratio ($<80\%$).^{1,2} Airflow limitation in asthma should be partially or completely reversible after inhaling a bronchodilator or after a 2-week trial of corticosteroids, with an improvement of at least 12% or 200 mL from baseline for FEV_1 or FVC considered to be clinically significant.² Failure to reverse should suggest other causes (especially COPD).

AIRWAY HYPERRESPONSIVENESS

Airway hyperresponsiveness (AHR) has been extensively assessed as an objective marker of asthma, as it is an important feature of the disease and is relatively easy to measure. In clinical practice, AHR is usually measured by methacholine or histamine challenges.

Most patients with symptomatic asthma show a fall in FEV_1 of $>20\%$ after inhalation of methacholine at a concentration ≤ 16 mg/mL.³ False-negative results may occur in patients who only experience symptoms at times of relevant allergen exposure and who are asymptomatic when tested.

The relevance of allergen or occupational exposures may be determined by direct airway challenge with a suspected allergen or irritant. However, this approach presents safety and practical difficulties, so its use is confined to specialist centers.

NONINVASIVE MARKERS OF AIRWAY INFLAMMATION

Airway inflammation can be indirectly assessed by measuring exhaled nitric oxide (NO)⁴ or carbon monoxide (CO), which are elevated in individuals with asthma. Exhaled NO varies with disease activity and in response to anti-inflammatory therapy; it is lower in patients treated with inhaled glucocorticosteroids. However, neither measurement is specific for asthma, as both may be elevated in other conditions associated with airway inflammation. Airway inflammation can also be assessed by examining sputum for eosinophils and other inflammatory cells and mediators.⁵

ASSESSMENT OF ATOPY

Measuring allergen-specific IgE adds little to the diagnosis of asthma, but can help to identify possible triggers. Results must be interpreted in the context of the patient's history: positive results do not necessarily mean that there is a causal relationship between allergen exposure and asthma symptoms.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of asthma includes various nonasthmatic causes of wheezing, cough and shortness of breath associated with airways obstruction. These include large airway obstructions (extrathoracic), located in the lumen (primary and rarely secondary neoplasms, foreign body), in the airway wall (neoplasms, glottic webs, vascular rings, post-traumatic injury, laryngeal nerve palsy, vocal cord dysfunction, tracheomalacia) or outside the wall (extrinsic compression by a neoplastic or inflammatory mediastinal mass such as enlarged lymph nodes). Medium and small airway obstruction (intrathoracic) may be due to luminal obstruction (mucus, pus, or a fungal plug), wall obstruction (mucus, gland, and/or muscle hypertrophy, muscle spasms, or oedema), or be extrinsic (peribronchial inflammation and loss of parenchyma). Multiple conditions lead to these abnormalities and cause subsequent airway narrowing. COPD, congestive heart failure, pulmonary venous hypertension and pulmonary embolism must be considered in adults. Eosinophilic lung disease/pulmonary infiltrates with eosinophilia may be of known cause (parasitic infestations, allergic bronchopulmonary mycosis, eosinophilia-myalgia syndrome, drug-induced eosinophilic pneumonias), or unknown cause (acute or chronic eosinophilic pneumonia, Loeffler's syndrome, hypereosinophilic syndrome and Churg-Strauss syndrome). In children, CF and bronchopulmonary dysplasia should be considered. Flow-volume loops (Fig. 40.1) are useful in distinguishing the type of obstruction, which may be confirmed by direct or indirect examination.

CLASSIFICATION OF SEVERITY

Asthma severity is classified on the basis of several criteria, including symptoms, medication use and lung function: these are used to define four grades of severity (intermittent, mild persistent, moderate persistent and severe persistent) (Table 40.1).¹ If the patient is already on therapy, the classification is based on the same clinical features combined with the maintenance treatment regimen (Table 40.2).¹

Table 40.1 Classification of asthma severity by clinical features before treatment

Asthma severity	Symptoms	Nocturnal symptoms	Lung function
Step 1 Intermittent	Symptoms < once a week Brief exacerbations (a few hours to a few days); variable severity Asymptomatic between exacerbations	≤ 2 times a month	FEV ₁ or PEF ≥ 80% predicted PEF or FEV ₁ variability < 20% Normal PEF between exacerbations
Step 2 Mild persistent	Once a week < symptoms < once a day Exacerbations may affect activity and sleep	> 2 times a month	FEV ₁ or PEF ≥ 80% predicted 20% < PEF or FEV ₁ variability < 30%
Step 3 Moderate persistent	Daily symptoms Exacerbations may affect activity and sleep; ≥ 2 times a week, may last days Daily use of inhaled short-acting β ₂ -agonists	> once a week	60% < FEV ₁ or PEF < 80% predicted PEF or FEV ₁ variability > 30%
Step 4 Severe persistent	Daily/continual symptoms Frequent exacerbations Limitation of physical activity	Frequent	FEV ₁ or PEF ≤ 60% predicted PEF or FEV ₁ variability > 30%

The presence of one of the features of severity is sufficient to place a patient in the respective category; an individual should be assigned to the most severe grade in which any feature occurs.

CLINICAL RELEVANCE

RISK FACTORS FOR FATAL OR NEAR-FATAL ASTHMA AND FOR ASTHMA EXACERBATIONS

Risk factors for fatal or near fatal asthma

Indicators of asthma severity (clinical and lung function)
 Previous history of life-threatening acute attacks (e.g. intubation, mechanical ventilation or respiratory acidosis)
 Previous hospital admission for asthma (especially if within the previous year)
 Repeated attendances to hospital emergency due to asthma exacerbations
 Need for the use of three or more groups of different asthma medications
 Heavy use of β_2 -agonists
 Recent reduction or cessation of corticosteroid therapy
 Behavioral and psychosocial problems
 Poor or no compliance with the medical therapy
 Regular failure to attend follow up appointments (hospital and general practitioner)
 Self-discharge from hospital
 Alcohol or drug abuse
 Psychosis, depression, other psychiatric illness
 Obesity
 Income or employment problems
 Learning difficulties
 Social isolation
 Childhood abuse

Exacerbating factors for asthma

Allergen exposure
 Inhalant indoor and outdoor, food allergens
 Air pollutants and irritants
 Meteorological factors
 Exercise and hyperventilation
 Psychological/emotional factors
 Drugs
 Foods and food additives
 Obesity
 Respiratory infections
 Rhinitis
 Sinusitis
 Gastro-esophageal reflux disease (GERD)
 Vocal cord dysfunction (VCD)

KEY CONCEPTS

GOALS OF ASTHMA MANAGEMENT AND ASTHMA MANAGEMENT STRATEGIES

Goals of asthma management – Asthma control

- >> Achieve and maintain control of symptoms (such as shortness of breath, cough, chest tightness)
 - minimal, ideally no daytime symptoms
 - minimal, ideally no nocturnal symptoms/awakenings
- >> Prevent asthma exacerbations (minimal/infrequent)
 - minimal β_2 -agonist need
 - no emergency visits
- >> Maintain normal activity levels, including exercise (no limitation)
- >> Maintain lung function as close to normal levels as possible
 - FEV₁ and PEF near normal
 - PEF variability (diurnal variation) <20%
- >> Avoid adverse effects from asthma medications (minimal or no)
- >> Prevent progression of the disease and development of irreversible airflow limitation
- >> Prevent asthma mortality

Asthma management strategies

- >> Assessment and monitoring of asthma severity
 - measurements of symptoms
 - measurements of lung function
- >> Identification and avoidance of exposure to potential risk and triggering factors
- >> Pharmacological treatment
 - design of individualised medication plans for long-term management in children and adults – regularly reviewed in accordance with a stepwise approach
 - establishment of individualised medication plans for the management of exacerbations
- >> Maintenance of regular follow up care
- >> Education of patients (helping them to understand their disease and to take active part in its management, improving adherence to the management strategy)

This assessment has important implications for management, as treatment is based on a stepwise approach, adjusted according to disease severity. Asthma severity may vary over time, and patients should be assessed periodically and reclassified so that their management can be adapted to their current needs.

It is important to emphasize that any asthmatic (even those with mild persistent disease) may have a severe exacerbation, which if not recognized and treated may prove fatal.¹ Several factors increase the risk for the development of fatal or near-fatal asthma (see Clinical Relevance).^{1, 6} Most patients who die from asthma have chronically severe or poorly controlled disease, with increased health service use and suboptimal self-management.⁶

MANAGEMENT GUIDELINES

Several guidelines using evidence-based methodology have been published over the last few decades, each being revised regularly to include the most up-to-date evidence.^{1, 7, 8} These guidelines contain similar recommendations: the basic principles include adequate diagnosis, identification of causal/triggering/exacerbating factors, assessment of severity, achieving rapid control, and maintaining such control (Key Concepts). Although the main objective of the guidelines is to improve knowledge and standards of clinical practice in the hope of improved outcomes, it must be emphasized that guidelines are flexible recommendations.

GOALS AND PRINCIPLES OF MANAGEMENT

Although asthma cannot be cured, in most patients adequate control can be achieved and maintained. The goals of asthma management are to achieve and maintain symptom control, maintain normal activity levels and lung function, and prevent exacerbations and progression of the disease.

STEPWISE MANAGEMENT OF ASTHMA

The core principles of asthma management are to identify and avoid potential risk and triggering factors, to use appropriate pharmacotherapy, to maintain regular follow-up with continuous monitoring of severity (adjusting treatment according to response). Pharmacological treatment should be individualized and regularly reviewed. The choice of medications is dictated by the severity of the disease and directed towards suppression of airway inflammation. Once control is achieved and sustained for at least 3 months, it can be stepped down to the appropriate level until the minimum therapy required to maintain control is achieved. Failure to gain control may indicate poor compliance or an incorrect diagnosis. Regular monitoring is an essential part of this approach. Figures 40.2 and 40.3 present the stepwise approach to achieve and maintain control of asthma in adults and in children.¹

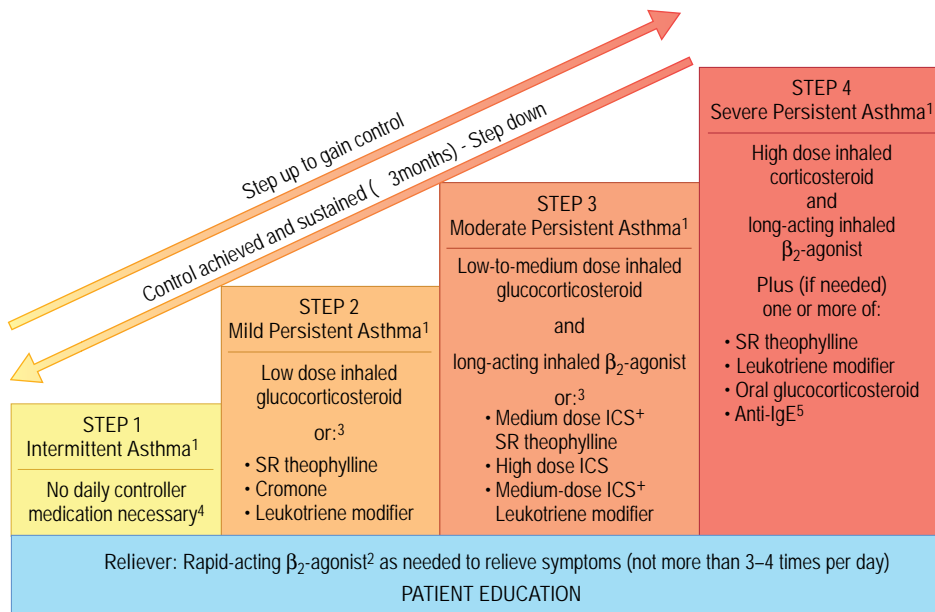

Fig. 40.2 Stepwise approach to asthma pharmacological management in adults and children older than 5 years. ICS, inhaled glucocorticosteroid; SR theophylline, slow-release theophylline. ¹See Tables 40.1 and 40.3 for classification of severity. ²Other options for reliever medication are (in order of increasing cost) inhaled anticholinergic, short-acting oral β_2 -agonist, and short-acting theophylline. ³Other treatment options listed in order of increasing cost. ⁴Patients with intermittent asthma but severe exacerbations should be treated as having moderate persistent asthma – Step 3 (Evidence D¹). ⁵Current evidence supports use in adults and children ≥ 12 years only. Management of acute asthma exacerbations. (Adapted with permission from the GINA Workshop Report (2005) - Global Strategy for Asthma Management and Prevention, available from <http://www.ginasthma.org>. Note: at the time of production of this book an updated/revised report was posted on the website, dated November 2006.)

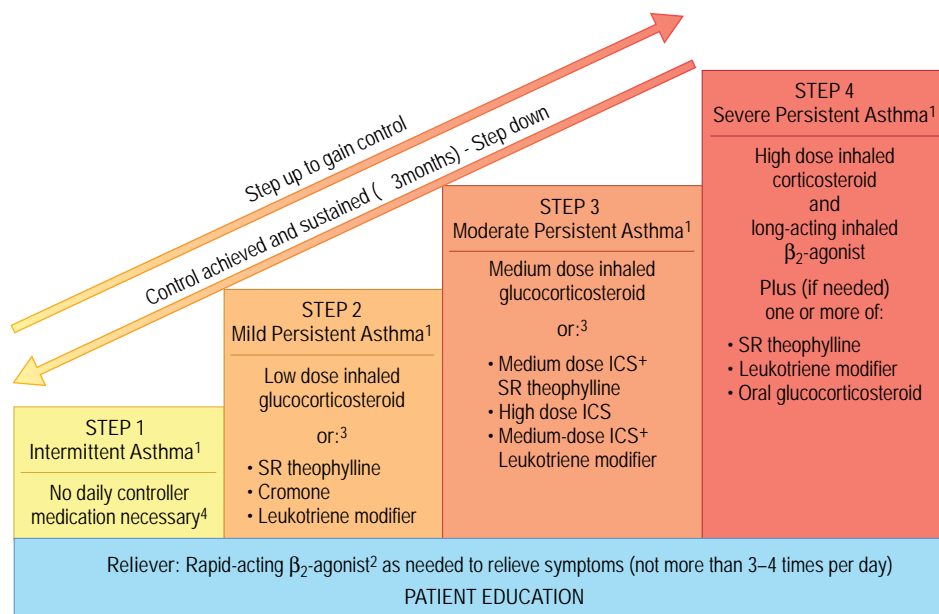

Fig. 40.3 Stepwise approach to asthma pharmacological management in children younger than 5 years of age. ICS, inhaled glucocorticosteroid; SR theophylline, slow-release theophylline. ¹See Tables 40.1 and 40.3 for classification of severity. ²Other options for reliever medication are (in order of increasing cost) inhaled anticholinergic, short-acting oral β_2 -agonist, and short-acting theophylline. ³Other treatment options listed in order of increasing cost. ⁴Patients with intermittent asthma but severe exacerbations should be treated as having moderate persistent asthma – Step 3 (Evidence D¹). (Adapted with permission from the GINA Workshop Report (2005) - Global Strategy for Asthma Management and Prevention, available from <http://www.ginasthma.org>. Note: at the time of production of this book an updated/revised report was posted on the website, dated November 2006.)

IDENTIFICATION AND MANAGEMENT OF TRIGGERING FACTORS

The objective of tertiary prevention is to prevent exacerbations, improve control and reduce medication needs. Factors that may trigger exacerbations and/or cause persistence of symptoms include exposures to allergens and occupational sensitizers, pollutants or drugs (e.g., aspirin). Many conditions can complicate asthma and interfere in its control by triggering exacerbations and increasing severity.

ALLERGEN AVOIDANCE

Exposure to allergens can trigger asthma attacks in sensitized individuals. Thus, environmental control measures designed to avoid allergen exposure should lead to an improvement in disease control. Several uncontrolled studies (e.g., prolonged stay at high altitude/hospitals) have suggested a clinical benefit of allergen avoidance. However, attempts to replicate these findings in patients' homes have proved difficult, at least partly because it is not easy to eradicate allergens completely.

- **Mites** A recent Cochrane meta-analysis concluded that mite allergen avoidance should not be recommended for mite-sensitive asthmatics.⁹ The largest randomized placebo-controlled trial assessing the effect of mite-impermeable bed covers involved over 1000 adult asthmatics

and showed convincingly that this single intervention is ineffective in long term.¹⁰ However, a large study from US inner-city areas showed that a comprehensive environmental control regimen tailored to patients sensitization and exposure status may be effective in asthmatic children.¹¹

- **Pets** No beneficial effect has been reported for pet avoidance measures in allergic asthma.¹²
- **Cockroaches** Avoidance measures, including eliminating suitable environments, restricting access, chemical control and traps, are only partially effective.
- **Fungi** The number of fungal spores can be reduced by removing or cleaning mold-laden objects and by maintaining low humidity. Air conditioners and dehumidifiers can reduce humidity and filter large fungal spores, lowering the mold count indoors; however, their benefit in terms of reducing symptoms is unclear.¹
- **Outdoor allergens** Outdoor allergens (e.g., pollens, molds) are impossible to avoid completely. Pollen and mold spore counts may help patients limit exposure to specific allergens by rescheduling outdoor activities.
- **Food allergens** Food allergy is an uncommon exacerbating factor for asthma, although respiratory symptoms may be triggered by food allergens in food-sensitized patients (usually as part of a systemic reaction). In individuals with confirmed food allergy, avoidance can reduce asthma exacerbations.

- **Occupational exposure** Many substances have been identified as occupational allergens. In industrialized countries, between 9% and 15% of all cases of adult-onset asthma may be due to occupational asthma, which is more common among workers in construction, metal work, rubber work, plastic work, printing and industrial cleaning industries (Chapter 49).

AIR POLLUTANTS AND IRRITANTS

- **Tobacco smoke exposure** Environmental tobacco smoke exposure increases the risk of asthma exacerbations and respiratory infections. Active smoking causes an accelerated decline in lung function among asthmatics, greater asthma severity, and reduces the efficacy of inhaled and systemic corticosteroids. Thus, smoking cessation should be vigorously encouraged, and parents of children with asthma should be advised not to smoke and not to allow smoking in their homes.
- **Other indoor air pollutants** Nitrogen oxides, carbon monoxide/dioxide, sulfur dioxide, formaldehyde, and biological materials such as endotoxins are associated with exacerbations. Avoiding exposure to these pollutants is difficult, and the effectiveness of most methods has not been appropriately evaluated.
- **Outdoor air pollutants** Diesel exhaust particles due to vehicle traffic, sulfur dioxide, ozone, and nitrogen oxides have been implicated in increasing the frequency and severity of exacerbations. In addition, airway responses to allergens are enhanced by concurrent exposure to air pollutants. Air pollutants may adhere to the surface of pollen allergens, modify their allergenic potency, and act as carriers, increasing allergen deposition in the lung. Furthermore, diesel exhaust can stimulate IgE production, which may promote allergic sensitization and respiratory diseases in susceptible individuals. Some measures can be taken to reduce exposure and minimize its consequences (e.g., avoiding physical activity during air pollution episodes).¹
- **Meteorological factors** Adverse weather conditions may have a direct effect on the airway (exercise in cold dry air), or indirect effects on air pollution (thermal inversion), and pollen/spore allergen levels (thunderstorms).

RESPIRATORY INFECTIONS

Viral respiratory infections are responsible for 80–85% of exacerbations in school-aged children and 60–75% among adults; rhinovirus is the main culprit.¹³ Acute viral respiratory infections may lead to persistent small airway obstruction (for weeks) and transient airway hyperreactivity in both normal and asthmatic individuals. Asthmatics have more severe and prolonged lower respiratory tract symptoms and greater reductions in lung function when infected than do healthy subjects. Virus infections also increase the effects of allergen exposure and air pollution on asthma.

The role played by bacterial infections has been less studied, but there is evidence suggesting that they may also trigger asthma. The most convincing data is for *Chlamydia pneumoniae*. *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Moraxella catarrhalis* have also been linked to exacerbations, particularly when sinusitis is present. An association has been reported between *Chlamydia* and *Mycoplasma pneumoniae* and both chronic asthma and acute exacerbations.¹⁴ However, this is controversial, with conflicting evidence due partly to the difficulty of diagnosing infection accurately.¹⁴

OTHER COMMON TRIGGERING FACTORS AND COMORBIDITIES

- **Exercise** This is one of the most common triggers of brief asthma symptoms. The mechanisms of exercise-induced asthma are not completely understood, but may involve hyperosmolarity or airway cooling and re-warming.¹⁵ Exercise rarely causes bronchoconstriction in normal individuals or patients with other respiratory conditions. Physical training programs can improve physical fitness, neuromuscular coordination and self-confidence; regular physical activity increases physical fitness and lowers ventilation during mild and moderate exercise, reducing the likelihood of provoking exercise-induced bronchospasm. Exercise training may also reduce the perception of breathlessness through a number of mechanisms, including strengthening the respiratory muscles.
- **Aspirin/NSAIDs** Aspirin and other non-steroidal anti-inflammatory drugs (NSAIDs) cause acute asthma exacerbations in 9–20% of adults with asthma and 34% of adults with asthma, nasal polyps and pansinusitis, but rarely in children. The mechanism is a temporary increase in the production and release of inflammatory mediators in the respiratory tract via inhibition of COX-1. This type of disease usually starts in the third or fourth decades of life with persistent and progressively severe rhinitis, which evolves into hyperplastic rhinosinusitis, followed by persistent asthma, aspirin/NSAID-induced respiratory reactions, and the aggressive formation of nasal polyps. Aspirin-sensitive asthma is more frequent in females, who tend to have an earlier onset and more severe disease. Stringent avoidance of aspirin and NSAIDs is essential, but the role of low-salicylate diets is controversial.
- **Foods and food additives** Several substances present in foods may trigger asthma symptoms in susceptible patients, including preservatives, salicylates, monosodium glutamate and coloring agents. Sulfites are found in many beverages (especially beer and wine) and processed foods, and have clearly been implicated as triggers for exacerbations.¹ The role of other substances in triggering asthma is more controversial. Dietary restrictions may be beneficial when sensitivity is confirmed by double-blind placebo-controlled challenge.
- **Obesity** Obesity may worsen asthma severity and reduce quality of life. Weight loss improves lung function, symptoms, morbidity and health status in obese asthmatics.
- **Rhinitis/sinusitis** Asthma and rhinitis commonly coexist and share epidemiological, histological, physiological and immunopathogenic characteristics.¹⁶ Nasal inflammation may significantly influence the lower airways, and vice versa; uncontrolled allergic rhinitis may lead to worsening of coexisting asthma.¹⁶ Optimal management of rhinitis may improve asthma control, reducing ER visits and hospitalizations.^{1, 16} Sinusitis may also complicate asthma and contribute to its severity; antibiotic treatment of bacterial sinusitis may improve asthma control.¹
- **Gastro-esophageal reflux disease (GERD)** GERD and asthma are frequently associated: it is estimated that GERD is present in 60–80% of asthmatic adults and 50–60% of asthmatic children. There is considerable debate regarding the nature of this association, but GERD appears to be an important trigger for asthma and a risk factor for worsening symptoms, asthma-related hospitalization, and a requirement for oral steroids.¹⁷ Some studies have shown that anti-reflux therapy improves asthma control in patients with symptomatic GERD.¹⁷ However, a

systematic review of 12 trials of medical and surgical anti-reflux treatments in children and adults found no overall improvement in asthma following treatment for GERD; subgroups of patients may benefit, but it is difficult to predict responders.¹⁸

- **Vocal cord dysfunction (VCD)** VCD may coexist with asthma and contributes to airway obstruction in up to 40% of asthmatics.

PHARMACOLOGICAL TREATMENT

Pharmacological treatment aims to reduce airway inflammation, improve symptom control, and prevent acute exacerbations while minimizing side effects. Adequate control should be achieved as soon as possible. Treatment should start at the step most appropriate to the initial asthma severity and then be reviewed regularly, stepping up and down according to the level of control.^{1, 7, 8} Anti-asthma drugs may be divided into 'controllers/preventers' (corticosteroids, leukotriene modifiers, cromones, methylxanthines and long-acting β_2 -agonists) and 'relievers' (short-acting β_2 -agonists, long-acting β_2 agonists cholinergic antagonists). Persistent asthma is better controlled by drugs that suppress and reverse airway inflammation than by reliever drugs.¹ Clinical trials suggest heterogeneity in the individual response to asthma drugs, largely attributable to genetic background. Future developments in pharmacogenetics may allow therapy to be tailored to each patient's response to medication.

CONTROLLERS: LONG-TERM PREVENTIVE MEDICATIONS

Controllers, also called prophylactic, preventive or maintenance medications, are taken daily on a long-term basis to treat inflammation and achieve/maintain asthma control (Table 40.3).

Inhaled glucocorticosteroids

Glucocorticosteroids (Chapter 87) are the most effective anti-inflammatory asthma drugs: inhaled corticosteroids (ICS) are the first-choice controller treatment in both children and adults.^{1, 7, 19} Glucocorticosteroids suppress airway inflammation, reduce AHR, control symptoms, improve quality of life and reduce morbidity and mortality.²⁰

Role in therapy

Episodic high-dose ICS are partially effective against episodes of mild viral-induced wheeze in children, but long-term low-dose ICS cannot prevent viral-induced wheeze. In addition, early treatment of childhood wheezing with ICS does not appear to prevent subsequent asthma.²¹

Pharmacology

Glucocorticosteroids differ in their potency and bioavailability after inhalation (Table 40.4). Dose comparisons of ICS are difficult owing to their long duration of action and relatively flat dose-response curves. The delivery device has a major impact on absorption, as without the use of a spacer 70–90% of the drug is deposited in the oropharynx; dry powder inhalers (DPI) are more efficient at delivering the drug to the lungs than pressurized metered-dose inhalers (pMDI). Improvement in asthma control occurs within days of starting ICS, but several months are necessary to attain the maximum effect. Once control is achieved, the dose should be carefully reduced to the minimum needed to maintain control, reducing the potential for side effects. Because asthma sometimes remits, ICS may be withdrawn for a trial period if the patient becomes asymptomatic for a prolonged period on low-dose treatment. Because the dose-response curve for ICS is relatively flat for most outcome measures (e.g., symptoms, lung function, airway responsiveness), using higher doses rarely improves asthma control, but increases the risk of side effects.

Adverse effects

The most common adverse effects of ICS are local, including oropharyngeal candidiasis, dysphonia, and occasional coughing due to upper airway irritation. These effects are dose dependent and can be minimized by using spacer devices and rinsing the mouth or gargling after each dose.¹ Dysphonia commonly responds to vocal rest and discontinuing ICS.

All currently available ICS are absorbed from the lung, although the extent of systemic exposure varies according to their dose and potency, bioavailability, gut absorption, first-pass liver metabolism and plasma half-life.²² The delivery system also affects the amount of systemic exposure: using a spacer reduces systemic absorption for most, but not all, ICS. Long-term treatment with high-dose ICS can cause skin thinning and easy bruising, adrenal suppression and decreased bone mineral density. Although differences exist between the various drugs and inhaler devices, treatment with doses <400 μ g beclomethasone/budesonide daily is not usually associated with significant suppression of the hypothalamopituitary-adrenal (HPA) axis in children; at higher doses (≥ 1000 μ g/day), small changes in HPA-axis function can be detected with sensitive methods. Whether these are clinically relevant remains unknown. Likewise, the question as to whether long-term ICS therapy suppresses growth in children is debatable. Dose-dependent growth retardation occurs with all ICS when sufficiently high doses are given. However, this is usually modest, transient, and unlikely to affect adult height (asthmatics treated with ICS have consistently been found to attain normal adult height).¹ However, uncontrolled or severe asthma does adversely affect final adult height.

The clinical significance of the decrease in bone formation and degradation during treatment with high doses of ICS is not yet known. Several studies have shown no effect on bone mineral density or rates of fracture.²³ Prophylactic treatment for osteoporosis is not advised for patients on ICS.¹

Table 40.3 Glossary of asthma medications

CONTROLLER LONG-TERM MEDICATIONS			
Name	Usual doses	Side effects	Comments
Glucocorticosteroids			
Inhaled	Beginning dose depending on asthma severity (see Table 40.5), then titrated down over 2–3 months to lowest effective dose once control is achieved	High daily doses may cause: skin thinning and bruises, rarely adrenal suppression. Local side effects: dysphonia and oropharyngeal candidiasis	Potential but small risk of side effects is well balanced by efficacy. Spacer/holding chamber with pMDIs and mouth washing after inhalation with DPIs decrease local side effects and systemic absorption. Preparations not equivalent on per puff or µg basis
Beclomethasone			
Budesonide			
Flunisolide			
Fluticasone			
Mometasone furoate			
Triamcinolone			
Tablets or syrups	For daily control use lowest effective dose 5–40 g of prednisone equivalent	Used long-term may lead to osteoporosis, hypertension, diabetes, cataracts, adrenal suppression, growth suppression, obesity, skin thinning, muscle weakness	Long-term use: alternate day a.m. dosing produces less toxicity. Short-term: 3–10 day courses are effective for gaining prompt control
Hydrocortisone			
Methylprednisolone			
Prednisolone			
Prednisone	For acute attacks 40–60 g daily in 1 or 2 divided doses for adults or 1–2 mg/kg daily in children		
Cromones			
Sodium cromoglycate	MDI 2 mg or 5 mg/puff, 2–4 inhalations, 3–4 times/day	Minimal side effects. Cough may occur upon inhalation	May take 4–6 weeks for maximum effects to be attained. Frequent daily dosing required
Nedocromil	MDI 2 mg/puff, 2–4 inhalations, 2–4 times/day	Cough may occur upon inhalation	Some patients unable to tolerate the taste
Methylxanthines			
Theophylline	Starting dose 10 mg/kg/day with 800 mg maximum in 1–2 divided doses	Nausea and vomiting are most common. Serious side effects occurring at higher serum concentrations: seizures, tachycardia, arrhythmias	Theophylline level monitoring is often required. Absorption and metabolism may be affected by many factors
Sustained-release tablets and capsules			
Leukotriene modifiers			
Montelukast (M)	Adults	Limited data; no specific side effects at recommended doses	The position of leukotriene modifiers in asthma therapy is not fully established. Additive benefit when added to glucocorticosteroids, though not as effective as long-acting β ₂ -agonists.
Pranlukast (P)	M: 10 mg/day; P: 450 mg bid		
Zafirlukast (Z)	Z: 20 mg bid; Zi: 600 mg qid		
Zileuton (Zi)	Children		
	M: 5 mg/day (6–14 yrs); 4 mg/day (2–5 yrs)		
	Z: 10 mg bid (7–11 yrs)		
Long-acting inhaled β₂-agonists			
Formoterol (F)	DPI	May cause tachycardia, anxiety, skeletal muscle tremor, headache, hypokalemia in overdose	Always use as adjunct to anti-inflammatory therapy
Salmeterol (S)	1 inhalation bid (F–12 µg; S–50 µg) pMDI F or S: 2 puffs bid		

Continued

Table 40.3 Glossary of asthma medications—Cont'd

CONTROLLER LONG-TERM MEDICATIONS			
Name	Usual doses	Side effects	Comments
RELIEVER MEDICATIONS			
Rapid-acting inhaled β_2-agonists			
Salbutamol/Albuterol	Differences in potency exist but all products are essentially comparable on a per puff basis.	Inhaled: tachycardia, skeletal muscle tremor, headache, and irritability.	Drug of choice for acute bronchospasm. Inhaled route has faster onset and is more effective than tablet or syrup.
Fenoterol	For prn symptomatic use and pre-treatment before exercise: 2 puffs pMDI or 1 inhalation DPI.	At very high dose: hyperglycemia, hypokalemia.	Increasing use, lack of expected effect, or use of > 1 canister a month indicate poor asthma control; adjust long-term therapy accordingly.
Metaproterenol	For asthma attacks: 4–8 puffs q1–4h, may administer q20min \times 3 with medical supervision or the equivalent of 5 mg salbutamol by nebulizer.	Systemic administration as tablets or syrup increases the risk of these side effects.	Use of \geq 2 canisters per month is associated with an increased risk of a severe, life-threatening asthma attack
Piributanol			
Terbutaline			
Anticholinergics			
Ipratropium bromide (IB)	IB: MDI 4–6 puffs q6h or q20 min in the emergency department;	Minimal mouth dryness or bad taste in mouth	May provide additive effects to β_2 -agonist but has slower onset of action.
Oxitropium bromide	Nebulizer 500 μ g q20min \times 3 then q2–4 hrs for adults and 250 μ g for children		Alternative for patients with intolerance to β_2 -agonists
Tiotropium bromide			
Short-acting theophylline			
Aminophylline	7 mg/kg loading dose over 20 min followed by 0.4 mg/kg/h continuous infusion	Nausea, vomiting, headache. Serious side effects occurring at higher serum concentrations: seizures, tachycardia, arrhythmias	Theophylline level monitoring is required. Obtain serum levels 12 and 24 hours into infusion. Maintain between 10–15 μ g/ml.

National Heart, Lung and Blood Institute, National Institutes of Health. NIH Publication No 97-4051. Available on http://www.nhlbi.nih.gov .)			

Cataracts and glaucoma have been reported in cross-sectional studies of adults using ICS, but there is no evidence of post-capsular cataracts in prospective studies.¹

Evidence that ICS affect the central nervous system is limited to isolated case reports of hyperactive behaviour, aggressiveness, insomnia and impaired concentration, which returned to normal after discontinuing ICS.¹

Systemic corticosteroids

Long-term systemic glucocorticosteroids may be required to control severe persistent asthma in adults, but their use is limited by the risk of significant adverse effects. If oral glucocorticosteroids (OCS) have to be administered long-term, clinicians should focus on measures that minimize their side

effects: oral preparations (prednisone, prednisolone, or methylprednisolone) are preferred to parenteral preparations because of their minimal mineralocorticoid effect, relatively short half-life and limited effects on striated muscle. OCS should normally be given as a single morning dose, either every day or on alternate days.¹ Patients with asthma on long-term OCS should receive preventive treatment for osteoporosis.¹

Although their onset of action is 4–6 hours, systemic corticosteroids are important in the treatment of severe acute exacerbations because they prevent progression of the exacerbation, reduce the need for emergency department visits or hospitalizations, prevent early relapse after emergency treatment, and reduce morbidity.¹ Oral therapy with prednisone, prednisolone or methylprednisolone is preferred to intravenous hydrocortisone and should be continued for 3–10 days.

Table 40.4 Estimated comparative daily dosages for inhaled glucocorticosteroids

Drug	Low daily dose (μg)		Medium daily dose (μg)		High daily dose (μg)	
	Adults	Children	Adults	Children	Adults	Children
Beclomethasone dipropionate – CFC	200–500	100–250	500–1000	250–500	>1000	>500
Beclomethasone dipropionate – HFA	100–250	50–200	250–500	200–400	>500	>400
Budesonide – DPI	200–600	100–200	600–1000	200–600	>1000	>600
Budesonide – nebulizer inhalation suspension		250–500		500–1000		>1000
Flunisolide	500–1000	500–750	1000–2000	750–1250	>2000	>1250
Fluticasone	100–250	100–200	250–500	200–400	>500	>400
Mometasone furoate	200–400		400–800		>800	
Triamcinolone acetonide	400–1000	400–800	1000–2000	800–1200	>2000	>1200

(Adapted with permission from the GINA Workshop Report (2005) Global Strategy for Asthma Management and Prevention, available from <http://www.ginasthma.org>. Note: at the time of production of this book an updated/revised report was posted on the website, dated November 2006)

In children with asthma, systemic corticosteroids are only used for acute exacerbations, where they allow earlier discharge and fewer relapses.¹

Leukotriene modifiers

Leukotriene modifiers (LM) include cysteinyl leukotriene 1 (CysLT1) receptor antagonists (montelukast, pranlukast, zafirlukast), and 5-lipoxygenase inhibitors (zileuton).

Mechanism of action

Leukotrienes are 5-lipoxygenase products of arachidonic acid synthesized by mast cells, eosinophils and other inflammatory cells. Both LTB_4 and the cysteinyl leukotrienes (cysLTs: LTC_4 , LTD_4 , LTE_4) have been implicated in the pathogenesis of asthma. The cysLT are potent bronchoconstrictors and also have an effect on blood vessels, mucociliary clearance and eosinophilic inflammation. LTB_4 is a potent chemoattractant and cell activator for neutrophils and eosinophils. 5-lipoxygenase inhibitors prevent leukotriene synthesis. Leukotriene receptor antagonists block the CysLT1 receptors on airway smooth muscle and other cells. These drugs have some anti-inflammatory effects and a modest short-acting bronchodilator effect.^{1, 24}

Role in therapy

The effect of LM is less than that of low-dose ICS: they should only be used as monotherapy in highly selected patients with mild persistent asthma; they have been less extensively studied as monotherapy in children, but improve lung function and asthma control in children with moderate/severe asthma, though they have advantage of oral administration.¹ LM may allow reduced doses of ICS in patients with moderate/severe asthma, and improve disease control in patients uncontrolled

on ICS.¹ However, they are less effective than long-acting inhaled β_2 -agonists as add-on therapy, though they have the advantage of oral administration. LM are useful in patients with NSAID sensitivity, where there is overproduction of cysLTs (probably due to over-expression of LTC_4 -synthase).²⁴ LM are effective in preventing exercise-induced bronchoconstriction and may reduce the symptoms of allergic rhinitis coexisting with asthma.^{1, 24}

Adverse effects

LM are well tolerated and have few side effects. Zileuton has been associated with liver toxicity, and monitoring of liver function is recommended during treatment.^{1, 24} There are several reports of Churg–Strauss syndrome associated with LM therapy, but in most cases this occurred when systemic glucocorticosteroids were being reduced or withdrawn,^{1, 24} and a causal link is unlikely.

Cromones

Cromones (sodium cromoglycate and nedocromil sodium) are used as inhaled prophylactic treatment for mild persistent asthma, particularly in children. They have been available for over 30 years and have an excellent safety profile, but inferior efficacy to ICS.

Mechanism of action

How cromones work remains incompletely understood. There is some evidence that they partially inhibit IgE-dependent mediator release from human mast cells, and have selective suppressive effects on macrophages, eosinophils and monocytes. They also abolish or inhibit calcium channel activation triggered by cross-linking membrane-bound IgE by antigen and block chloride channels. Anti-inflammatory effects have been shown in sputum and bronchial biopsy studies. Cromones lack bronchodilator

activity, but may prevent or reduce bronchoconstriction following allergen or nonspecific challenges (exercise, cold air, sulfur dioxide, aspirin); they also prevent late responses to allergens and exercise.¹

Role in therapy

Sodium cromoglycate reduces symptoms, the frequency of exacerbations and the need for rescue medication. Lung function improves, but benefits on AHR have not been consistently demonstrated. A recent meta-analysis of 24 studies concluded that cromoglycate is not significantly effective in asthmatic children.²⁵ Nedocromil used before exercise reduces the severity and duration of exercise-induced bronchoconstriction. However, short-acting β_2 -agonists and LMs are more effective.

Adverse effects

Cromones have minimal side effects. Occasional coughing, throat irritation and bronchoconstriction occur in a few patients; some patients find nedocromil tastes unpleasant, or report headache and nausea.

Methylxanthines

Theophylline has been available for over 50 years and remains widely prescribed for asthma. Its role has been questioned because of the frequency of side effects and relatively low efficacy; however, because it is effective, inexpensive, and widely available, several guidelines still recommend it. In richer countries it has largely been superseded by newer therapies. The most common marketed salt is aminophylline, which can also be used intravenously.

Mechanism of action

Both the mechanism and site of action remain uncertain. Several molecular mechanisms have been proposed, though many only operate at concentrations above those used clinically. These include nonselective phosphodiesterase (PDE) inhibition, adenosine receptor antagonism, stimulation of catecholamine release, mediator inhibition (prostaglandins, TNF- α), inhibition of intracellular calcium release, decreased nuclear translocation of NF- κ B, and increased histone deacetylase activity. The primary effect of theophylline is assumed to be relaxation of the airway smooth muscle, which is related to PDE inhibition and seen at high concentrations (>10 mg/L); however, theophylline is a weak bronchodilator at therapeutic concentrations. Most studies show little or no effect on AHR. Theophylline may have extrapulmonary effects, including anti-inflammatory effects (demonstrable at lower concentrations [5–10 mg/L]), but whether this significantly affects chronic airway inflammation is unknown.

Role in therapy

Sustained-release theophylline and aminophylline can be used as controller medications for asthma in both adults and children.¹ Sustained-release formulations of methylxanthines are useful in controlling nocturnal symptoms and as additional bronchodilators in patients with severe asthma. They may be used as add-on therapy (adding theophylline to ICS provides better

asthma control than increasing ICS doses),¹ and although less effective than inhaled long-acting β_2 -agonists,²⁶ theophylline is much cheaper.

Owing to the risk of adverse effects and the difficulty of monitoring therapy, theophylline is used in some countries after ICS and β_2 -agonists fail to achieve therapeutic goals, but elsewhere it is recommended at an earlier stage.

Sustained-release products are preferred for maintenance therapy as they enable twice-daily dosing in most patients (particularly in children, who metabolize theophylline very rapidly and may require dosing 4–6 times/day with plain formulations). Concomitant food intake unpredictably affects the absorption of some theophylline products; preparations with reliable absorption profiles and complete bioavailability when taken with food are available.¹

Adverse effects

One of the main limitations of theophylline is the frequency of adverse effects that are dose dependent and usually occur at concentrations exceeding 10 mg/kg body weight/day. These can generally be avoided by appropriate dosing and monitoring. Gastrointestinal symptoms (nausea and vomiting) are the most common early adverse effects, along with headaches. At higher concentrations theophylline can cause seizures and even death; these events may not be preceded by obvious central nervous system stimulation. Tachycardia, arrhythmias, and occasionally respiratory stimulation occur. Generally, serious toxic effects do not occur at serum concentrations <15 mg/L. Usual practice during long-term treatment is to aim for a steady-state serum concentration of 5–15 mg/L (28–85 μ mol) for adults.¹ There is still considerable debate regarding optimal plasma levels for children; maximum bronchodilator effect is achieved at plasma levels of 10–20 mg/L (55–110 μ mol),¹ but measurable effects on other outcomes may be achieved at lower concentrations (e.g. anti-inflammatory effects). So it seems reasonable to individualize the dose according to clinical effects rather than aiming for specific plasma levels. Theophylline metabolism and clearance vary with age and other factors such as multiple drug interactions, pregnancy and other conditions. Monitoring serum concentrations is advised when starting high-dose theophylline therapy (10 mg/kg/day or above) and at occasional intervals thereafter, as well as when patients develop adverse effects on their usual dose, when expected therapeutic aims are not achieved, or when situations known to alter theophylline metabolism occur.

Long-acting inhaled β_2 -agonists

Long-acting inhaled β_2 -agonists (LABAs) (formoterol, salmeterol) are selective β_2 -agonists with an extended duration of action of more than 12 hours. They act by reversing and/or inhibiting bronchoconstriction and related symptoms of acute asthma, but do not reverse airway inflammation or reduce hyperresponsiveness.^{1, 27}

Mechanism of action

Activation of β_2 -adrenergic receptors induces smooth muscle relaxation, enhanced mucociliary clearance, decreased vascular permeability, inhibition of cholinergic neurotransmission and inhibition of mediator release from mast cells, basophils and other inflammatory cells.²⁷ Formoterol is a full β_2 -agonist with a short onset of action (2–3 minutes) and a maximum effect 30–60 minutes after inhalation, whereas salmeterol is a partial

agonist and has delayed onset of action (~10–20 minutes), with maximal effect attained within 1–3 hours. Owing to its rapid onset of action formoterol may be suitable for symptom relief, although this role needs further investigation.¹ LABAs protect against several bronchoconstrictive stimuli (e.g., histamine, methacholine, cold dry air and exercise).²⁷

Role in therapy

LABAs should be considered in patients with moderate/severe asthma that is not controlled despite standard doses of ICS.¹ LABAs reduce asthma symptoms, frequency of nocturnal symptoms and exacerbations, decrease bronchodilator requirements, and improve lung function and asthma-specific measures of quality of life.^{1,27} As long-term treatment with LABAs does not appear to reduce the persistent airway inflammation, LABAs should *always* be combined with ICS.¹ Adding LABAs in patients whose asthma is not controlled on either low or high doses of ICS results in better control of the disease than doubling the ICS dose.¹ Fixed combination inhalers (fluticasone propionate + salmeterol, budesonide + formoterol) are convenient for patients. Although LABAs may be useful in children, there is insufficient evidence to support their general use in this age group.¹

Adverse effects

Tremor is the major side effect, caused by stimulation of β_2 receptors in skeletal muscle. β_1 -receptor stimulation may lead to increased heart rate and palpitations, prolonged QT interval, arrhythmias and myocardial ischemia. β -adrenergic relaxation of vascular smooth muscle reduces peripheral resistance, leading to reflex sympathetic cardiac stimulation. Acute metabolic responses to β_2 -agonists include hyperglycemia, hypokalemia and hypomagnesemia: these diminish with regular administration.²⁷ Tolerance develops with regular administration of β_2 -agonists, presumably due to β_2 -adrenergic receptor downregulation.²⁷ This is found for both bronchodilator and metabolic effects; a reduced bronchodilator response develops over a few weeks, and once established it is stable with continued use of the drug (this principally affects duration of action and broncho-protection rather than the peak effect).²⁷

A recent large study comparing the safety of salmeterol or placebo added to usual asthma care in patients over 12 years of age showed a small but significant increase in asthma-related deaths in patients receiving salmeterol.²⁸ It was not clear whether this was directly due to the LABA or to other factors (e.g., physiologic treatment effects, genetic factors, or patient behavior). Thus far it remains uncertain whether ICS can limit or prevent the adverse outcomes (i.e., subjects underwent randomization without consideration of their corticosteroid therapy, and no records of ICS therapy were kept). A thorough analysis by the FDA concluded that the data from the SMART study are inconclusive as regards this point.²⁹

RELIEVER MEDICATIONS

Relievers or rescue medications (Table 40.3) include rapid-acting bronchodilators that relieve bronchoconstriction and its associated symptoms.

Short-acting β_2 -agonists

Short-acting inhaled β_2 -agonists (SABAs) induce prompt bronchodilation and provide rapid symptom relief. They include salbutamol (albuterol), terbutaline, fenoterol, reproterol and pirbuterol.

Mechanism of action

SABAs relax airways smooth muscle and have other nonbronchodilator effects related to the stimulation of β_2 -adrenergic receptors²⁷ (see LABAs above). They can be administered via inhaled, oral, subcutaneous or intravenous routes. The inhaled route is preferred, as it allows more rapid bronchodilation with fewer side effects. Inhaled SABAs provide significant protection against exercise-induced bronchoconstriction; their effects start within 5 minutes of administration and last 3–6 hours. Oral preparations are used in patients unable to use inhaled medication (e.g., young children).

Differential responses to SABAs have been described among asthmatic patients with different β_2 -adrenergic receptor gene alleles; the clinical implications of this finding require further examination.

Role in therapy

SABAs are the medication of choice for episodic acute symptoms and for acute severe asthma in adults and children; premedication prevents exercise-induced asthma.¹ SABAs should be used as required for symptom control. Increased SABA use or decreased response to SABAs indicates the need to institute or intensify regular anti-inflammatory therapy.

Adverse effects

See section on LABAs.

Anticholinergics

Inhaled anticholinergics (ipratropium bromide, oxitropium bromide, tiotropium bromide) are short-acting bronchodilators.

Mechanism of action

These drugs block the stimulation of muscarinic cholinergic receptors (functionally selective for receptors M_1 and M_3) by acetylcholine released from autonomic nerves in the airways.³⁰ They also block reflex bronchoconstriction caused by inhaled irritants, but have no effect on the early- and late-phase allergic reactions or airway inflammation. In asthma, they are less potent bronchodilators than SABAs¹ and have a slower onset of action (60–90 minutes to achieve maximum effect). The duration of action of ipratropium and oxitropium is 4–8 hours, whereas tiotropium lasts for >24 hours.³⁰

Role in therapy

Anticholinergics provide complete protection against bronchospasm induced by cholinergic agonists (e.g., methacholine) and β -blocking agents, but only partial protection against other bronchoconstrictors.

In acute severe asthma, nebulized ipratropium adds to the effects of nebulized SABAs with a modest improvement in lung function and reduced risk of hospital admission.³¹ The benefits of ipratropium in the long-term management of asthma have not been established, although it is a useful alternative bronchodilator for patients who experience adverse effects from SABAs.¹ A subset of asthmatics may respond more favorably to anticholinergics, although it is not possible to predict response other than by therapeutic trial.³²

Ipratropium helps in the management of acute exacerbations, as its effects are additive to those of SABAs, providing a greater and more rapid improvement in lung function and avoiding prolonged emergency treatments and hospitalization.³³ Tiotropium is a new longer-acting anticholinergic that is useful in COPD, but its role in asthma has yet to be defined.

Adverse effects

Anticholinergics have a wide therapeutic margin and are well tolerated.³⁰ They have few side effects, as gastrointestinal absorption is minimal, and they do not cross the blood–brain barrier. Dry mouth is the commonest side-effect, but is rarely sufficiently severe to warrant discontinuation. Other occasional complaints are a bad taste, transient cough and paradoxical bronchoconstriction.³⁰

Other drugs used as relievers

Methylxanthines

Short-acting theophylline preparations may be considered for relief of symptoms (although their onset of action is slower than SABAs).¹ Although they provide no additive bronchodilator effect over adequate doses of SABAs, theophyllines may improve respiratory muscle function and prolong or sustain the response to SABAs.¹ In adults with acute asthma, intravenous aminophylline did not result in any additional bronchodilatation compared to standard care with β -agonists, and was associated with more adverse effects; no patient subgroups were identified in which aminophylline might be more effective.³⁴ However, in children, adding intravenous aminophylline to SABAs and glucocorticosteroids (with or without anticholinergics) improved lung function, although symptoms, treatment requirements and length of hospital stay were not reduced.³⁵

OTHER PHARMACOLOGICAL AGENTS

Anti-IgE

Mechanism of action

Since IgE plays an important role in the pathophysiology of asthma, chelating IgE seems a logical therapeutic approach. Omalizumab is a recombinant humanized IgG₁ monoclonal anti-IgE antibody that binds to IgE in the region that binds IgE receptors (Fc ϵ RI and Fc ϵ RII), preventing IgE from interacting with them. Omalizumab is not anaphylactogenic, as it cannot cross-link IgE molecules bound to basophils or mast cells. Instead, it binds to circulating IgE forming small biologically inert IgE–anti-IgE complexes that do not activate complement or cause the formation of anti-omalizumab antibodies.³⁶ Omalizumab attenuates the early- and late-phase responses after allergen challenge, decreases eosinophil numbers in sputum and bronchial submucosa, and downregulates Fc ϵ RI expression on basophils, mast cells and dendritic cells.³⁶

Role in therapy

The role of omalizumab in asthma management has yet to be precisely defined.³⁷ At present, the principal indication is as add-on therapy in patients with moderate to severe allergic asthma,¹ although its use is limited by its cost.^{1, 37} Patients who are particularly likely to benefit include those sensitized to perennial aeroallergens who require high doses of ICS, those with frequent exacerbations, and possibly those with severe symptoms related in part to poor adherence.³⁶ Patients requiring daily OCS to control their asthma may be less likely to respond.³⁶

Adverse effects

Anti-IgE appears safe and well tolerated.^{1, 36, 37} Reported adverse effects include rash, diarrhea, nausea, vomiting, epistaxis, menorrhagia, fatigue, arthralgias, dizziness and injection-site reactions.³⁶ The safety profile needs further evaluation after long-term use. Potential concerns include the risk of developing malignancies and anaphylaxis. Cancer appears to develop more often in patients receiving anti-IgE than in those taking placebo, and anti-IgE is probably best avoided in patients with a personal or family history of cancer until this risk is better understood. Anaphylaxis has occurred within 2 hours of administration of omalizumab in three patients without other identifiable triggers; patients should therefore be observed in an appropriate setting after injection.³⁶

Macrolide and ketolide antibacterial agents

Macrolides (azithromycin, clarithromycin, erythromycin and roxythromycin) are broad-spectrum antibiotics active against a wide range of bacteria, including *Chlamydia pneumoniae* and *Mycoplasma pneumoniae*. Ketolides are structurally related to macrolides, with a broader range of antibacterial activity; telithromycin is the first ketolide approved for clinical use. Macrolides and ketolides have anti-inflammatory and immunodulatory activity (including suppression of neutrophilic inflammation). Trials of macrolides in chronic stable asthma showed positive effects on symptoms and eosinophilic inflammation, although the small number of patients included (357 patients in five studies) limits the generalizability of these findings.

Current guidelines do not recommend antibiotics for the treatment of acute exacerbations, as viruses are usually responsible. However, continuing interest in the potential role of *Chlamydia* infection in asthma has prompted a study of telithromycin in acute exacerbations in 278 adults (TELICAST).³⁸ Significant improvements were reported in symptoms and lung function in patients receiving telithromycin, but there was no greater effect in patients with evidence of infection compared to those without, so the mechanisms remain unclear.³⁸

Steroid-sparing agents

Several options have been tried to reduce OCS requirements in patients with severe asthma who experience significant side effects and in asthmatics who are steroid resistant defined as failure to improve FEV₁ by >15% of predicted after 7–14 days of OCS [prednisolone 20 mg twice daily]. Some steroid-resistant patients may respond to higher doses of OCS administered for longer periods, but

CLINICAL PEARLS

CHOICE OF INHALER DEVICE FOR CHILDREN

Age group	Preferred device	Alternative device
< 4 years	pMDI + dedicated spacer with face mask	Nebulizer with face mask
4–6 years	pMDI + dedicated spacer with mouthpiece	Nebulizer with face mask
> 6 years	DPI or breath-activated pMDI or pMDI + spacer with mouthpiece	Nebulizer with mouthpiece

(Adapted with permission from the GINA Workshop Report (2005) Global Strategy for Asthma Management and Prevention, available from <http://www.ginasthma.org>. Note: at the time of production of this book an updated/revised report was posted on the website, dated November 2006)

such courses are unacceptable owing to the adverse effects. Therapeutic options include methotrexate, cyclosporine, gold, intravenous immunoglobulin and troleandomycin. These medications should only be used in carefully selected patients under close supervision, as they have a very narrow therapeutic window and their potential steroid-sparing effect may not outweigh the risk of serious adverse effects. A meta-analysis of methotrexate studies concluded it has a small steroid-sparing effect, but the reduction in steroid dose is probably insufficient to materially alter the risk of steroid side effects and offset the adverse effects of methotrexate.³⁹

Cyclosporine and gold were judged to induce small changes of questionable significance and, given the incidence of adverse effects, they are no longer recommended as steroid-sparing agents. Reviews of colchicine,⁴⁰ chloroquine⁴¹ and dapsone⁴² concluded that there is insufficient evidence to support their use as steroid-sparing drugs. Troleandomycin alters the metabolism of steroids, allowing a lower dose of methylprednisolone to be used, but may not reduce side-effects.

INHALER DEVICES

A wide range of devices is available to deliver drugs to the lung. When choosing an inhaler device, physicians should consider the efficacy of drug delivery, cost-effectiveness, safety, convenience, patient's age and ability to use the device. Pressurized metered-dose inhalers (pMDI) require training and skill to coordinate activation and inhalation. Spacers (holding chambers) improve drug delivery and reduce oropharyngeal deposition, thereby reducing systemic absorption and the risk of side effects.¹ Breath-actuated aerosols may be helpful for patients who have difficulty coordinating the pMDI. Dry powder inhalers (DPI) do not require propellants and are generally easier to use than pMDIs, but may be difficult to use during exacerbations.

Nebulizers are not preferred for maintenance treatment, as they are expensive, bulky, and require maintenance; furthermore, they deliver variable doses unless equipped with a dosimeter. It is important to emphasize that even for administration of inhaled β_2 -agonists during exacerbations, pMDIs with a spacer are the devices of choice, rather than nebulizers. A systematic review comparing MDI + spacer versus nebulizer delivery of SABAs in acute severe exacerbations showed equivalent clinical outcomes in adults, but the system was superior in children.¹ Simplicity of operation is especially important for treating infants and preschool children with MDI + spacer.

Whichever device is selected, patients should be instructed in its use, and their technique should be checked regularly.

FUTURE TRENDS IN ASTHMA TREATMENT

The role of specific immunotherapy in treating asthma is controversial, not least because the risk of adverse effects is much greater in patients with asthma than in those with rhinitis. Several new forms of immunotherapy are under development, which may improve the risk:benefit ratio (Chapter 93).

Various anti-cytokine strategies have been proposed and tested in asthma. TNF- α has been implicated in the pathogenesis of asthma, and in particular in the remodeling process that accompanies chronic severe asthma. A recent study in refractory asthma suggested upregulation of TNF- α , which might contribute to corticosteroid refractoriness.⁴³ An open study of TNF blockade with the soluble fusion protein etanercept reported improvement in asthma symptoms, lung function and quality of life, paralleled by a marked reduction in AHR.⁴⁴

IL-4 is critical in the development of IgE but has several other actions relevant to asthma. Several approaches to IL-4 antagonism have been assessed in clinical trials, although none has yet proved very effective.⁴⁵ These include soluble humanized IL-4 receptors, a humanized anti-IL-4 monoclonal antibody, and a mutated form of IL-4 receptor that acts as a competitive antagonist of both the IL-4 and IL-13 receptors.⁴⁵ IL-4 and IL-13 signal through a shared surface receptor (IL-4 receptor α) that activates a specific transcription factor signal transducer and activator of transcription (STAT-6); this led to a search for inhibitors of STAT-6, and although peptide inhibitors that interfere with the interaction between STAT-6 and Janus kinases linked to the IL-4 receptor α have been discovered, it has proved difficult to deliver these intracellularly. Another potential target is suppressor of cytokine signaling (SOCS-1), a potent inhibitor of IL-4 signaling pathways.⁴⁵

Intravenous infusion of anti-IL-5 antibodies (mepolizumab) markedly reduced the infiltration of eosinophils in peripheral blood and airway, but had no effect on the early or late response to allergen challenge or the baseline AHR, and proved ineffective in symptomatic asthma.⁴⁵ There is some evidence that blocking IL-13 might be more effective. Alternatively, using anti-inflammatory cytokines such as IL-10, IL-12, IL-18, IL-23 and interferon- γ might offer therapeutic potential.⁴⁵

Several inhibitors of chemokine receptors are in development (e.g., antibodies that block IL-8; chemokine CC3 receptor antagonists). Moreover, inhibitory agents of the synthesis of multiple cytokines are also in clinical development.⁴⁵

Another potential area for intervention is the range of adhesion molecules (selectins and their ligands, integrins, tissue matrix proteins, and members of the immunoglobulin gene superfamily) that have been identified through research into asthmatic airway inflammation. PSGL-1, ICAM-1, VCAM-1 and their ligands are all potential targets for asthma and allergy therapies because of their likely involvement in T-cell, mast cell, basophil, and eosinophil trafficking.

■ NONPHARMACOLOGICAL INTERVENTIONS ■

DIETARY MANIPULATION

Dietary interventions, such as supplementation with magnesium, sodium, antioxidants (vitamin C and selenium), omega-3 fatty acids, and calorie-controlled diets have been attempted, but in only a few controlled studies. Several Cochrane reviews have concluded that there is currently little evidence to support their use.

ALTERNATIVE/COMPLEMENTARY MEDICINE

The therapeutic efficacy of complementary/alternative treatments for asthma is not supported by currently available evidence. There is no evidence to allow any firm conclusion on the effect of herbal remedies on asthma. A Cochrane review on the role of acupuncture found no evidence of any benefit in asthma. Systematic reviews of several other unconventional approaches, such as homeopathy, manual therapy (physiotherapy, respiratory therapy, chiropractic and osteopathic techniques), psychological interventions, family therapy, relaxation therapies, and even speleootherapy, have been performed, all showing limited or no conclusive evidence of a benefit.

■ PATIENT EDUCATION AND FOLLOW-UP ■

Education is critical to ensure that patients understand the basic facts about asthma and its management, and take an active role in its control. Regular follow-up is essential to monitor symptoms and lung function, review treatment plans, inhaler technique, risk factors and methods to control them, all with the aim of ensuring that therapeutic goals are met and asthma control is achieved and maintained. The most appropriate method for follow-up will depend on the local healthcare system. A patient visit to a primary healthcare or specialist office, an outreach worker visit to patients' homes, or follow-up for asthma that is integrated with a visit for another reason can each be effective in providing ongoing care.¹

Patient education and training should be a continual process, with the objective of providing patients and their families with adequate information so that they can successfully achieve control of the disease, adjust the medication as necessary according to a tailored plan, identify and avoid modifiable triggering factors, manage exacerbations, and maintain a satisfactory quality of life. The emphasis should be on developing an

CLINICAL RELEVANCE

FACTORS INVOLVED IN NONCOMPLIANCE AND STRATEGIES FOR ITS IMPROVEMENT

Factors involved in noncompliance

Drug factors

Difficulties with inhaler devices
Awkward regimens (e.g. four times daily or multiple drugs)
Side effects
Cost of medication
Dislike of medication
Distant pharmacies

Nondrug factors

Misunderstanding or lack of instruction
Fears about side effects
Dissatisfaction with health care professionals
Unexpressed/undiscussed fears or concerns
Inappropriate expectations and underestimation of severity
Poor supervision, training, or follow-up
Anger about condition or its treatment
Cultural issues
Stigmatization
Forgetfulness or complacency
Attitudes toward ill health
Religious issues

Improving compliance

Compliance can be increased if the patient (or caretaker):

- >> Accepts the diagnosis of asthma
- >> Believes that this condition may be dangerous or is a problem and that he or she may be at risk
- >> Believes that the treatment is safe and effective
- >> Feels in control
- >> There is good communication and understanding between patient and healthcare professional

(Adapted with permission from the GINA Workshop Report (2005) Global Strategy for Asthma Management and Prevention, available from <http://www.ginasthma.org>. Note: at the time of production of this book an updated/revised report was posted on the website, dated November 2006)

ongoing partnership between healthcare professionals, the patient, and the patient's family. Education should focus on information regarding the disease process, its diagnosis, therapy and monitoring; patients should be taught the reasons for using the medications and the differences between 'relievers' and 'controllers,' and should receive regular training on the use of the inhaler devices. They should receive advice regarding preventive measures, detailed information on the signs and symptoms that suggest that asthma is worsening, and a contingency action plan for exacerbations, including criteria for initiating additional medicines, as well as advice on when and how to seek medical attention. Patients should be provided with written self-management plans having the most relevant information.

Table 40.5 Classification of severity of asthma exacerbations

Parameter	Mild	Moderate	Severe	Respiratory arrest imminent
Breathlessness	Walking	Talking; infant: softer, shorter cy, difficulty feeding	At rest infant stops feeding	
Speech	Sentences	Phrases	Words	Drowsy or confused
Alertness	May be agitated	Usually agitated	Usually agitated	Paradoxical
Respiratory rate	Increased <i>Guide to rates of breathing associated with respiratory distress in awake children</i>	Increased <i>Age</i> <i><2 months</i> <i>2–12 months</i> <i>1–5 years</i> <i>6–8 years</i>	Often >30/min <i>Normal rate</i> <i><60/min</i> <i><50/min</i> <i><40/min</i> <i><30/min</i>	Paradoxical
Accessory muscle use	Usually not	Usually	Usually	Thoraco–abdominal movement
Wheeze	Moderate, often only end expiratory	Loud	Usually loud	Absence of wheeze
Heart rate (bpm)	<100 <i>Guide to limits of normal heart rate in children</i> <i>Infants</i> <i>Preschool children</i> <i>School age children</i>	100–120 <i>Age</i> <i>2–12 months</i> <i>1–2 years</i> <i>2–8 years</i>	>120 <i>Normal rate</i> <i><160/min</i> <i><120/min</i> <i><110/min</i>	Bradycardia
PEF After initial bronchodilator % predicted or % personal best	>80%	~60–80%	<60% 100 l/min in adults Or response lasts <2 hours	
P _a O ₂ (on air)	Normal (arterial blood gases not usually necessary)	>60 mmHg	<60 mmHg Possible cyanosis	
P _a CO ₂	<45 mmHg	<45 mmHg	>45 mmHg Possible respiratory failure	
Sat O ₂ % (on air)	>95%	91–95%	<90%	

*The presence of several parameters but not necessarily all indicate the severity of the attack.

Note: at the time of production of this book an updated/revised report was posted on the website, dated November 2006)

Education should be provided to patients of all ages, in a personalized fashion, over several consultations or visits. Revision and reinforcement are essential components of education provided by the healthcare professional, and a full discussion of expectations and expression of fears and concerns should be allowed.

A systematic review of 36 trials showed that compared with usual care patient education delivers significant benefits in terms of reduced morbidity and use of health services; the effects are greatest when the intervention includes written self-management action plans.⁴⁶

COMPLIANCE

Noncompliance may be defined in a nonjudgmental way as failure to take treatment as agreed by the patient and the healthcare professional. Studies of adults and children across a broad range of diseases suggest noncompliance rates of around 50% with taking of regular preventive therapies.¹ Noncompliance may be identified by prescription monitoring, pill counting or drug assay, but at a clinical level it is best detected by asking about therapy in a way that acknowledges the likelihood of incomplete compliance.

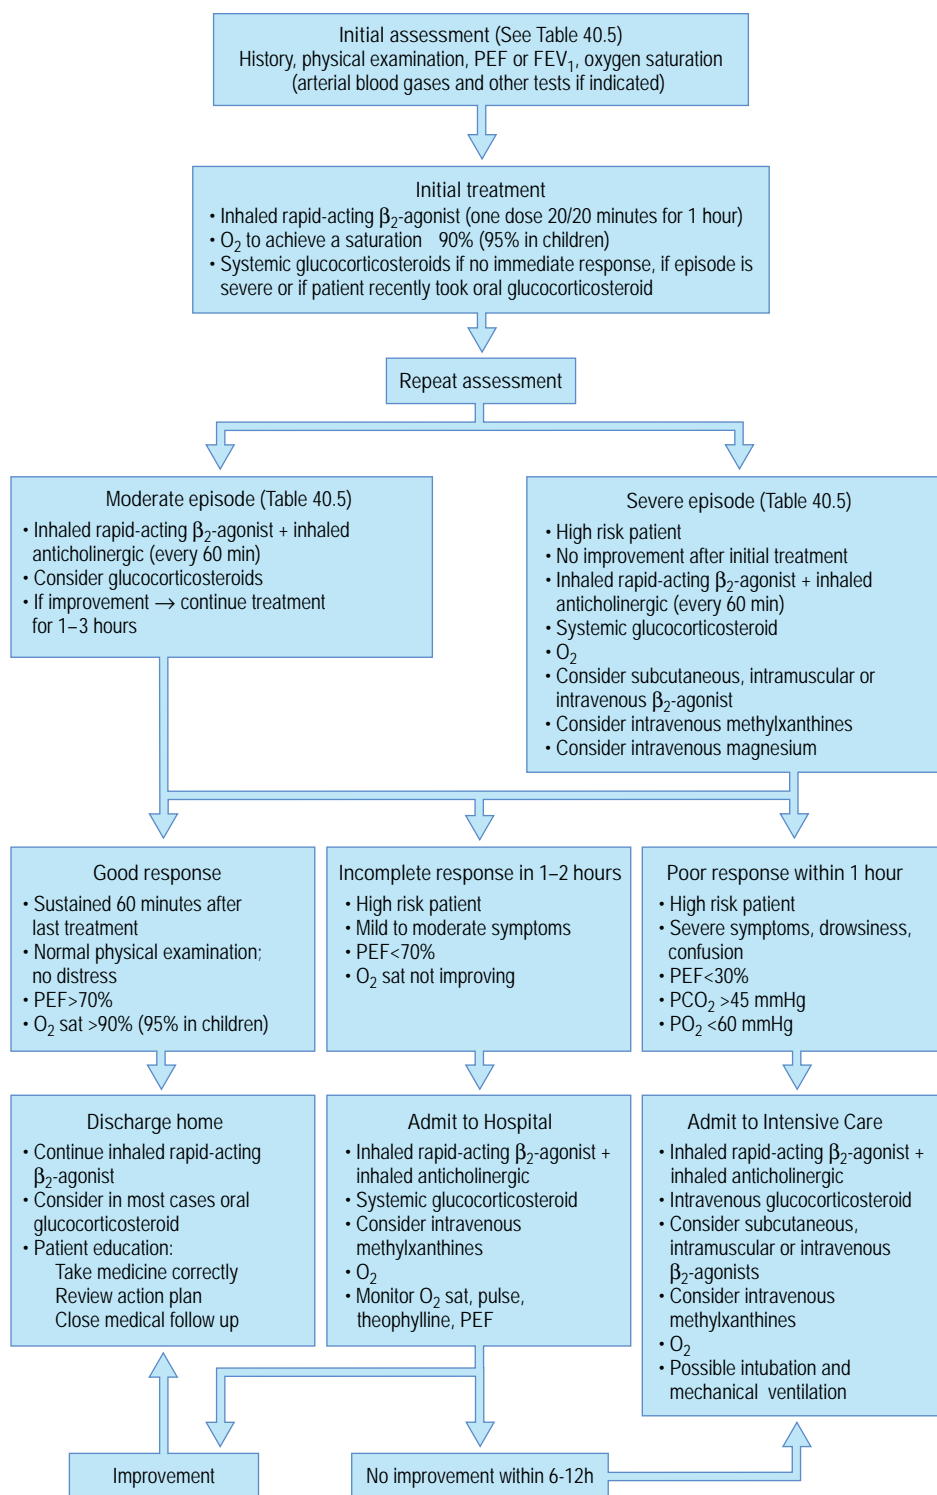

Fig. 40.4 Management of acute asthma exacerbations. (Adapted with permission from the GINA Workshop Report (2005): Global Strategy for Asthma Management and Prevention, available from <http://www.ginasthma.org>. Note: at the time of production of this book an updated/revised report was posted on the website, dated November 2006.)

MANAGEMENT OF ACUTE EXACERBATIONS

Acute exacerbations of asthma are what patients are most concerned about. Typically there is a progressive increase in shortness of breath, cough, wheezing, or chest tightness, or a combination of these symptoms. Exacerbations may come on gradually or over a very short timescale. The degree of exacerbation can be quantified by measuring reductions in expiratory airflow (PEF or FEV₁). Acute severe exacerbations can be life-threatening and may occur in patients at all levels of severity (see Box 40.1), and warrant prompt assessment and treatment (Table 40.5 and Fig. 40.4). In most patients deterioration progresses over hours or days, allowing action to be taken to mitigate the attack, but occasionally they can occur precipitously over a few minutes. A fatal outcome is most often associated with failure to recognize the severity of the exacerbation, inadequate action at its onset, and subsequent under-treatment.

Repeated administration of inhaled SABAs remains the mainstay of treatment, being the most effective means of relieving airflow obstruction.¹ Adding an anticholinergic drug provides more effective bronchodilatation than a β_2 -agonist alone, resulting in a greater and more rapid improvement in lung function, avoiding prolonged emergency treatments and hospitalization.³³ Systemic glucocorticosteroids should be given early in the course of the exacerbation, even though they take some hours to become effective.¹ Oxygen should always be given, and careful attention paid to oxygen saturation. Deteriorating oxygen saturation or rising arterial CO₂ despite appropriate therapy are indications for ventilatory support. Once over the acute episode, careful review of the circumstances leading up to the exacerbation may help identify issues that could help to prevent future relapses.

CONCLUSION

Asthma management is based first on an accurate diagnosis, including the identification of specific and nonspecific triggers. Avoidance of potential risk and triggering factors is important, but unlikely to lead to resolution. As well as starting appropriate pharmacological therapy, patients should be educated on the nature and treatment of asthma, and how to recognize early signs of exacerbation. Pharmacological treatment should be individualized and tailored to the patient; it should be regularly reviewed and adjusted in a stepwise approach to achieve maximum control and minimize side effects. With appropriate management virtually all people with asthma should be able to control their condition and live full and productive lives.

Rhinitis and sinusitis

Mark S. Dykewicz

41

Rhinitis and sinusitis are among the most common medical conditions, and frequently coexist.^{1–6} In western societies it is estimated that 10–25% of the population suffer from allergic rhinitis.^{1–3} In the US, sinusitis affects about 31 million patients annually.⁶ Both rhinitis and sinusitis can have a tremendous adverse impact on individuals and society. They can significantly reduce quality of life, aggravate comorbid conditions and require significant medical expenditure. Both conditions create an even greater indirect cost to society by reducing workplace productivity and learning in school, and by causing a tremendous number of absences from work and school.

RHINITIS

Although the term ‘rhinitis’ connotes inflammation of the nasal mucous membranes, some rhinitis disorders are not always characterized by inflammatory cell infiltrates. Instead, rhinitis can be viewed clinically as a heterogeneous group of nasal disorders characterized by one or more of the following: nasal congestion, rhinorrhea, nasal itching and sneezing. Rhinitis can be caused by allergic, nonallergic, infectious, hormonal, occupational, and other factors.^{1,2} Although allergic rhinitis is the most

common type of chronic rhinitis, nonallergic rhinitis has been reported to account for 30–70% of patients with chronic perennial rhinitis.¹

NASAL ANATOMY AND PHYSIOLOGY

The nasal cavity is partitioned by the nasal septum, a structure formed from cartilage distally and bone proximally.³ The lateral aspects of the nasal cavity contain the inferior, middle, and superior turbinates, important for humidification, temperature regulation and air filtration (Fig. 41.1). The nasal cavity is lined with mucosa composed of pseudostratified columnar ciliated epithelium that overlies a basement membrane and the submucosa (lamina propria). The submucosa contains serous and seromucous nasal glands and an extensive network of blood vessels, nerves and cellular elements. Because the nasal tissues are highly vascular, vascular changes can play a prominent role in nasal obstruction. Covering the nasal epithelium is a thin layer of mucus that is transported by ciliary action to the posterior nasopharynx. [IM1]

Sympathetic nerve stimulation causes vasoconstriction and resultant decreases in nasal airway resistance to airflow. Conversely, parasympathetic nerve stimulation can increase nasal congestion and resistance, but more importantly upregulates the secretion of mucus from nasal mucosal glands. Nonadrenergic, noncholinergic (NANC) neuropeptides (substance P, neurokinins A and K, neuropeptide tyrosine and calcitonin gene-related peptide) have a putative role in promoting vasodilatation, mucus secretion, plasma extravasation, neurogenic inflammation, and mast cell nerve interactions, but their relative clinical importance is not yet defined.^{1,3} Alterations in the autonomic tone of the nasal vasculature cause side-to-side fluctuation in nasal engorgement and airflow, called nasal cycling, with period lengths ranging from approximately 1 to 5 hours.

PATHOPHYSIOLOGY OF ALLERGIC RHINITIS

As with allergic asthma, allergic rhinitis can be caused by a variety of airborne protein and glycoprotein allergens from pollens, molds, dust mite fecal particles, cockroach residues and animal danders. After inhalation of allergenic particles, allergens are eluted in nasal mucus and subsequently

CLINICAL PEARLS

RHINITIS

- >> At least one-third of perennial rhinitis patients have no allergic basis.
- >> Nasal corticosteroids are the most effective drug class for allergic rhinitis.
- >> Food-induced rhinitis in adults is usually a cholinergic response, and rarely involves IgE-mediated food allergy.
- >> Nasal corticosteroids and oral antihistamines have similar effectiveness in relieving eye symptoms associated with allergic rhinitis.

Fig. 41.1 Nasal anatomy. (Modified from: Adkinson NF Jr, Yunginger JW, Busse WW, et al. *Middleton's allergy principles and practice*, 6th edn. Philadelphia: Mosby, 2003; 1412.)

diffused into nasal tissues. In addition, inhaled, small molecular weight airborne chemicals (e.g., from occupational exposures or drugs) can act as haptens when they react with self proteins in the airway to form complete allergens. In nasal tissues, the sensitization process is initiated when antigen-presenting cells (dendritic cells, especially CD1⁺ Langerhans'-like cells, and macrophages) present allergen to CD4 T lymphocytes.⁷ Next, stimulated CCR3⁺ CD4⁺ T cells, with possible contribution by CD8 Tc2 cells, release IL-3, IL-4, IL-5, IL-13, and other cytokines which produce a cascade of events that promote local and systemic IgE production by plasma cells; chemotaxis; and inflammatory cell recruitment, localization, proliferation, activation, and prolonged survival within the airway mucosa.^{3,8} CD8 Tc1 cells that release IFN- γ , possibly activated by IL-15, can inhibit initiation of the process.⁹

Early/immediate allergic response

Within minutes of exposure of sensitized individuals to allergens, IgE-mediated degranulation of mast cells and basophils causes the release of pre-formed mediators such as histamine and tryptase, and de novo generation of other mediators, including cysteinyl leukotrienes and prostaglandin D₂ (PGD₂)^{1,3} (Chapter 22). Mediators induce leakage of plasma from blood vessels and dilation of arteriole venule anastomoses, with resultant edema, blood pooling in the cavernous sinusoids (the predominant cause of the perceived congestion), and occlusion of nasal passages. Mediators also stimulate the secretion of mucus from goblet and glandular cells. Histamine is the principal mediator responsible for itching, rhinorrhea, and sneezing, whereas other mediators such as leukotrienes and PGD₂ probably play a greater role in the development of nasal congestion.¹ The perception of nasal itching and congestion occurs via stimulation of sensory nerves, whereas sneezing paroxysms are triggered by systemic neurogenic reflexes.¹

Late-phase response

Mediators and cytokines released during the early phase trigger a cascade of events over the following 4–8 hours which culminate in inflammatory responses that characterize the late-phase response. Although the clinical

features of the immediate and late responses are similar, nasal congestion becomes more prominent in the late response.^{1–3} Mediators and cytokines produced during the early response upregulate expression of cell adhesion molecules, such as vascular cell adhesion molecule (VCAM1) and E-selectin on post-capillary endothelial cells. As a result, circulating leukocytes adhere to the endothelium as part of the inflammatory process. Inflammation is further promoted by chemoattractant factors, including IL-5, that promote infiltration of the superficial lamina propria of the mucosa by eosinophils, neutrophils and basophils, and eventually CD4 (Th2) lymphocytes and macrophages.¹ The inflammatory cascade progresses as these cells become activated and release further mediators, which in turn activate other proinflammatory responses. Ultimately eosinophils predominate in nasal secretions, whereas CD4 (Th₂) lymphocytes predominate in nasal biopsy specimens.¹⁰

RELATIONSHIP BETWEEN RHINITIS AND ASTHMA

Asthma and rhinitis are comorbid conditions that are associated both epidemiologically and pathophysiologically.^{1–3, 11} (Table 41.1). More than 80% of persons with allergic asthma have allergic rhinitis (AR), and AR is a risk factor for the development of asthma.¹ Guidelines recommend that patients with persistent AR should be evaluated for asthma, and patients with asthma should be evaluated for rhinitis.¹

CLINICAL PRESENTATION OF DIFFERENT TYPES OF RHINITIS

In addition to the four classic symptoms of AR (rhinorrhea, nasal congestion, sneezing, nasal itching), patients with AR commonly experience symptoms of conjunctivitis (eye pruritus, lacrimation, chemosis) [IM4].¹ Postnasal drip occurs commonly, as do associated symptoms involving the ears, eyes, and throat. Symptoms of AR frequently overlap with symptoms associated with other forms of rhinitis and various anatomic abnormalities of the upper airway.

Nonallergic rhinitis without eosinophilia, variably termed vasomotor rhinitis (VMR) or idiopathic rhinitis,^{1–3} is not caused by allergic or infectious processes, but is probably a heterogeneous group of disorders whose pathogenesis is incompletely understood. Nasal obstruction and/or rhinorrhea are prominent symptoms, with sneezing and pruritus being less common. The term VMR is sometimes used more selectively to indicate nasal symptoms that occur in response to nonallergic environmental stimuli, such as changes in temperature or relative humidity, perfumes, cleaning materials, tobacco smoke, alcohol ingestion and sexual arousal. Such hyperreactivity to nonallergic triggers may also occur in AR, a clinical picture that is sometimes termed 'mixed rhinitis.' In recent years, computerized tomography (CT) has revealed that many patients diagnosed with VMR do in fact have chronic sinusitis or other disorders.⁴

Nonallergic rhinitis with eosinophilia syndrome (NARES) is characterized by perennial nasal symptoms and typically presents with prominent nasal congestion, sneezing paroxysms, profuse watery rhinorrhea, nasal pruritus, and occasional loss of smell.^{1–3} Nasal smears demonstrate eosinophils, but patients are not allergic to environmental allergens. It has been proposed that NARES may be an early stage of aspirin sensitivity.

Hormonal rhinitis can be caused by hormonal changes of pregnancy, menstrual cycle, puberty, or thyroid disorders.^{1–3} During pregnancy,

Table 41.1 Comparative immunopathology and pathophysiology of allergic rhinitis and asthma (Modified from Gelfand EW. Inflammatory mediators in allergic rhinitis. *J Allergy Clin Immunol* 2004; 114: S135–138 with permission from Elsevier.)

Similarities	Differences
Similar immunologic processes	Nose (ectodermal) and bronchial (endodermal) airways have a different embryologic origin.
Similar pathologic findings in nasal and bronchial tissue	Genes governing repair-remodeling might be different.
Eosinophils, mast cells, Th2 lymphocytes	Smooth muscle is only present in the bronchi.
Early- and late-phase responses	Nose contains a large supply of subepithelial capillaries, arterial systems, and venous cavernous sinusoids.
Hyperresponsiveness: sensorineural in nasal passages and airways in response to allergen challenge	

congestion and other rhinitis symptoms can develop *de novo* during the second month of gestation and continue to term, but usually resolve shortly after delivery. However, most pregnant women with nasal symptoms have pre-existing rhinitis that may worsen, improve, or remain the same during pregnancy.¹

Drug-induced rhinitis can be induced by either oral and topical medications.^{1–3} Causal oral medications include ACE inhibitors, β -blockers, various other antihypertensive agents, aspirin and other cyclo-oxygenase-1 inhibitors, oral contraceptives or conjugated estrogens. The use of topical α -adrenergic decongestant sprays for more than 5–7 days may induce rebound nasal congestion upon withdrawal (rhinitis medicamentosa). Repeated use of intranasal cocaine and methamphetamines may also result in rebound congestion, and occasionally septal erosion and perforation.

IgE-mediated sensitivity is rarely responsible for rhinitis caused by food ingestion, in the absence of reactions involving other organ systems.^{1–3} Ethanol can produce nasal symptoms via nasal vasodilation.¹ Gustatory rhinitis is a cholinergically mediated syndrome of postprandial watery rhinorrhea that may be more pronounced after eating hot and spicy foods, and becomes more common with age.

DIFFERENTIAL DIAGNOSIS OF RHINITIS

Acute viral upper respiratory infection presents with nasal symptoms and constitutional symptoms (fever, myalgias, malaise), but pruritus is typically absent and symptoms usually resolve within 7–10 days.^{4–6} Acute and chronic bacterial sinusitis may be difficult to distinguish clinically from rhinitis (see Sinusitis below).

Anatomic abnormalities (e.g., septal deviation, nasal polyps) usually present with prominent obstructive symptoms but less in the way of rhinorrhea. Septal deviation, albeit often asymptomatic, may cause unilateral or bilateral congestion. Diagnosis may be made by observing external deviation of the nose or examining the anterior nasal cavity, but may require fiberoptic rhinopharyngoscopy or CT scanning.

Other differential diagnoses for nasal symptoms include nasal tumors (benign or malignant) that commonly present with obstruction.^{1–3} Nasal carcinoma may present with unilateral epistaxis and nasal pain. Juvenile angiofibromas often present with bleeding in adolescent males. Young children may have intranasal foreign bodies (e.g. toy parts, or foods such as peanuts) causing a foul-smelling, purulent discharge and unilateral

nasal obstruction that predisposes to sinusitis. Adenoidal hypertrophy causes bilateral nasal obstruction in young children, with associated nocturnal mouth-breathing and snoring. Systemic diseases that cause nasal symptoms include Wegener's granulomatosis, which may present with nasal and sinus complaints, including purulent rhinorrhea and septal ulcerations and perforations; sarcoidosis, which may present with nasal congestion; and Sjögren's syndrome, which may cause nasal dryness, congestion, and crusting.

CSF rhinorrhea usually develops either immediately or within a few months of trauma, although it may occur spontaneously. Typically it presents with a unilateral, clear, watery discharge. The discharge often tests positive for glucose, although β_2 -transferrin is more sensitive and specific.¹²

DIAGNOSIS

History

The history should include specific symptoms that trouble the patient (e.g., nasal congestion, pruritus, rhinorrhea, sneezing); symptom patterns (seasonal or perennial, intermittent or persistent); precipitating factors; response to previous medications; coexisting conditions (e.g., asthma, sinusitis, otitis); and a detailed environmental history, including home and occupational exposures.^{1–3} In distinguishing allergic from nonallergic rhinitis, nasal itching, eye pruritus and lacrimation make allergy more likely. Because in most temperate regions trees pollinate in the spring, grasses in the late spring and early summer, and weeds in the late summer and fall, a corresponding history of seasonal symptoms suggests allergy. However, in certain regions molds and some pollens may cause perennial symptoms. Although allergens such as house dust mites, cockroaches, and animals cause perennial symptoms, approximately one-third of patients with perennial rhinitis have no underlying allergy. Family history is an important clue in making the diagnosis of AR in children.

Physical examination

Nasal examination can be performed with a handheld otoscope or nasal speculum that permits viewing of the anterior third of the nasal airway, including the anterior tip of the inferior turbinates (and occasionally the

anterior tip of the middle turbinates) and portions of the nasal septum.¹⁻³ However, fiberoptic rhinoscopy may be required to visualize other abnormalities, such as nasal polyps, septal deviation, or masses. Typically, patients with AR have a clear discharge, swollen turbinates, and bluish or pale mucosa. Pale or erythematous mucosa can be seen in various types of nonallergic rhinitis. Both allergic and nonallergic rhinitis can cause 'allergic shiners,' infraorbital darkening attributed to chronic venous pooling, or a persistent horizontal crease across the nose in children who rub their noses upward because of nasal discomfort – the so-called 'allergic salute.' In association with rhinitis, the presence of mild bilateral conjunctivitis is suggestive of allergy. Patients with nasal disease require appropriate examination for associated diseases, such as sinusitis, otitis media and asthma.¹⁻³

Diagnostic testing

Testing for specific IgE antibodies to allergens is important when avoidance measures or immunotherapy are being considered, and is of particular importance in perennial rhinitis, where it is more difficult to distinguish allergic or nonallergic rhinitis on the basis of history. Although *in vitro* tests are improving and approaching skin testing in sensitivity (Chapter 100), in a large randomized trial skin-prick tests had a better positive predictive value (48.7%) for the diagnosis of AR than did *in vitro* testing (Phadiatop) (43.5%).¹³

The presence of eosinophils in nasal cytology may aid in differentiating AR and NARES from other forms of rhinitis, such as vasomotor or infectious rhinitis, provided the correct procedure is followed and the appropriate stains are used.¹⁻³

In selected cases, special techniques such as fiberoptic nasal endoscopy, inspiratory peak flow measurements, acoustic rhinometry, or rhinomanometry to assess airway function may be useful in evaluating patients presenting with rhinitis symptoms. Nasal endoscopy permits direct visualization of abnormalities of the septum, turbinates, mucosa, nasopharynx, adenoids, and eustachian tube orifice.

TREATMENT

Avoidance measures

Avoidance of inciting factors, such as allergens (house dust mites, molds, pets, pollens, cockroaches), irritants, and medications, can effectively reduce symptoms of rhinitis.^{1,2} Exposure to outdoor allergens can be reduced by keeping windows closed, using an air conditioner, and limiting the amount of time spent outdoors. Measures to reduce house dust mite exposure should focus on use of allergen-impermeable casings on the bed and pillows, including polyester pillows.¹⁻³

Medications

As some medications are more effective for treating certain types of rhinitis or rhinitis symptoms, or more suitable for episodic rather than continuous use, the selection of medications should be individualized, taking into account the symptoms most troublesome to a patient, their severity, and whether they are episodic or more persistent, the likely underlying cause(s) of rhinitis, cost-effectiveness and patient preference.^{1,2} The AR guidelines published by the American Academy of Allergy, Asthma, and Immunology in conjunction with 20 other

organizations, is a stepped approach that considers symptom severity, intermittent or persistent disease, and whether medications are best used on a daily or an as-needed basis (Fig. 41.2).¹⁴ The Allergic Rhinitis in Asthma (ARIA) guidelines¹ advocate a conceptually consistent scheme for management based on the severity of rhinitis and whether symptoms are *intermittent* (defined as present <4 days per week or <4 weeks' duration) or *persistent* (present on >4 days per week or >4 weeks' duration).¹

Oral antihistamines

Acting as competitive inhibitors for H₁ receptors, oral antihistamines act to reduce rhinorrhea, sneezing, and nasal pruritus associated with AR, but have less effect on nasal congestion.¹⁻³ Antihistamines are effective when taken occasionally for episodic symptoms, but work best when administered regularly. Antihistamines are a first-line therapy for milder AR,^{1,2} but have little role in treating nonallergic rhinitis syndromes. First-generation antihistamines (e.g., diphenhydramine and chlorpheniramine) can cause perceived sedation and unperceived impairment of mental functioning, and are associated with automobile accidents, decreased work performance and productivity, and impairment of children's learning and academic performance.^{1-3,15} They can also cause anticholinergic side effects, such as dry mouth and urinary retention. Second-generation antihistamines, which are associated with less risk (cetirizine) or no risk for these side effects compared to placebo (e.g., desloratadine, loratadine, fexofenadine), should usually be considered before sedating antihistamines for the treatment of AR.^{1,2}

Oral decongestants

Through their α -adrenergic vasoconstrictor effects, oral decongestants (e.g., pseudoephedrine, phenylephrine) reduce nasal congestion produced by allergic and nonallergic forms of rhinitis.^{1,2} However, they may cause insomnia, nervousness, loss of appetite, urinary retention, and may aggravate cardiac arrhythmias, hypertension, and manifestations of hyperthyroidism.

Topical decongestants

Topical decongestant nasal sprays (e.g., oxymetazoline, phenylephrine) reduce nasal congestion in both allergic and nonallergic rhinitis, but should be limited to short-term use (e.g., 3–10 days) to avoid rebound nasal congestion (rhinitis medicamentosa).^{1,2} When there is significant edema of inferior nasal mucosal structures that would impair delivery of other nasal sprays to more superior/posterior regions of the nose, guidelines advocate use of a nasal decongestant spray during the first several days of treatment with other nasal sprays in order to improve drug delivery and effectiveness.²

Intranasal antihistamines

Intranasal azelastine is effective in the treatment of AR and vasomotor rhinitis.¹⁻³ It is at least as effective as oral antihistamines, but less effective than nasal glucocorticoids.¹⁶ It has some effect on nasal obstruction, but less than intranasal glucocorticoids. Side effects may include a bitter taste and sedation.

Please refer to the printed publication.

Fig. 41.2 Stepped management of allergic rhinitis. This stepped approach for treatment of seasonal allergic rhinitis considers symptom severity, intermittent or persistent disease, and whether medications are best used on a daily or as-needed basis. Although this figure depicts recommendations for seasonal allergic rhinitis, recommendations for perennial allergic rhinitis are similar. (From Rhinitis. In: The allergy report. Vol. 2. Diseases of the atopic diathesis. American Academy of Allergy, Asthma and Immunology, Milwaukee, 2000. p 20. Online. Available: http://www.aaaai.org/ar/working_vol2/020.asp 31 July 2006.)

Intranasal corticosteroids

Possessing a broad array of anti-inflammatory effects, intranasal corticosteroids are the most effective medication class for treatment of AR.^{1-3, 15} Moreover, they are also useful in some forms of nonallergic rhinitis. Nasal corticosteroids and oral antihistamines have similar effectiveness in relieving eye symptoms associated with AR.¹⁷ Modern preparations are not associated with significant systemic side effects in adults. Growth suppression in children has been associated with intranasal beclomethasone,¹⁸ but not from several other nasal corticosteroid preparations.^{19, 20} Local nasal irritation and bleeding may occur. The nasal septum should be examined periodically to assure that there are no mucosal erosions that may precede the development of perforations, which may rarely occur from intranasal corticosteroid use.² Although these drugs are most effective when given on a

regular schedule, some agents have a demonstrated onset of effect within 24 hours or less,^{1, 2} and PRN use of fluticasone nasal has been demonstrated to be more effective than PRN use of oral loratadine for seasonal AR.²¹

Leukotriene receptor antagonists

In addition to their efficacy for treatment of asthma, leukotriene receptor antagonists (montelukast, zafirlukast) have been demonstrated to have benefit for all principal symptoms of AR.²² By meta-analysis, these drugs are equivalent to oral histamine H₁ antagonists, but inferior to intranasal corticosteroids for seasonal AR. The combination of leukotriene receptor antagonists and histamine H₁ antagonists is statistically inferior to intranasal corticosteroids for relief of nasal congestion.²² There is a low incidence of side effects with this class of drugs.

CLINICAL PEARLS

SINUSITIS

- >> An acute upper respiratory illness sinusitis of less than approximately 7 days' duration is most commonly caused by viral illness, whereas bacterial sinusitis becomes more likely beyond 7–10 days.
- >> Many cases of chronic sinusitis are not caused by bacterial infections, and antibiotic treatment is of unproven benefit.
- >> 'Sinus headaches' are not typically caused by chronic sinusitis, but more commonly by migraines.
- >> Anosmia in chronic sinusitis is suggestive of nasal polyps.

Intranasal cromolyn

Intranasal cromolyn sodium is beneficial in allergic but not nonallergic rhinitis, but is less effective than oral antihistamines or intranasal antihistamines and intranasal corticosteroids.^{1,2} Optimally administered four to six times daily, nasal cromolyn should ideally be started before major symptoms develop during a season, as it may take several weeks to be fully effective. It can also be used for acute prophylaxis before exposure to a known allergen. Cromolyn has an excellent safety profile.

Intranasal ipratropium

Intranasal ipratropium bromide is an anticholinergic agent effective in reducing rhinorrhea in AR, nonallergic rhinitis, and viral upper respiratory infections, but has no benefit for other rhinitis symptoms.^{1–3} Ipratropium can provide acute prophylaxis against rhinorrhea triggered by known stimuli (e.g., food in gustatory rhinitis). It does not cause significant systemic anticholinergic effects.

Systemic corticosteroids

Short-acting oral corticosteroids (e.g., prednisone, methylprednisolone) are used in brief courses (e.g., prednisone 30 mg/day for 3–7 days for adults) for the treatment of very severe or intractable nasal symptoms.² The use of parenteral corticosteroids is discouraged because of their greater potential for suppression of the hypopituitary–adrenal (HPA) axis and long-term corticosteroid side effects.²

ALLERGEN IMMUNOTHERAPY/ALLERGY VACCINATION

Allergen immunotherapy may be highly effective in controlling the symptoms of AR, and can favorably modify the long-term course of the disease.^{1–3,23} AR patients should be considered candidates for immunotherapy on the basis of the severity of their symptoms, failure or unacceptability of other treatment modalities, presence of comorbid conditions, and possibly as a means of preventing the condition worsening or the development of comorbid conditions (e.g., asthma, sinusitis).^{1,2,23}

SINUSITIS

Sinusitis is classically defined as inflammation of one or more of the paranasal sinuses, air-filled cavities in facial bones lined with pseudo-stratified ciliated columnar epithelium and mucous goblet cells. The term rhinosinusitis is increasingly used in recognition that rhinitis (whether allergic or nonallergic) typically accompanies sinusitis.^{5,6} Sinusitis without rhinitis is rare, the mucosa of the nose and sinuses are anatomically contiguous, and symptoms of nasal obstruction and discharge are prominent in sinusitis.⁴ In the following discussion, the terms sinusitis and rhinosinusitis will be used interchangeably, a reflection of the varying preference for use of these terms in cited medical literature.

According to major national and international guidelines, acute sinusitis is defined as lasting less than 4 (or 12) weeks, whereas chronic sinusitis persists longer than 12 weeks.^{4–6} In some guidelines, disease of 4–12 weeks' duration is termed subacute.⁴ Recurrent sinusitis refers to repeated episodes of acute sinusitis, typically more than three times per year, often further defined to require the absence of intervening signs and symptoms of chronic rhinosinusitis.⁴

SINUS ANATOMY AND PHYSIOLOGY

Epithelial cilia in the sinuses normally beat in an orderly fashion to move mucus towards the ostia that communicate with the nasal cavity. Rather than draining through simple ostia, the anterior ethmoid, maxillary, and frontal sinuses drain through a comparatively convoluted and narrow drainage pathway, the ostiomeatal complex, which communicates into the middle meatus, between the inferior and middle turbinates (Fig. 41.3). Obstruction of the ostiomeatal complex is thought to be particularly important in promoting some forms of persistent sinus disease. The posterior ethmoid sinuses drain into the upper meatus, whereas the sphenoid sinuses drain into the posterior wall in the sphenoethmoidal recess. The ethmoid sinuses consist of a 'honeycomb' of cells lying medial to the orbital structures and varying between four and 17 air cells in number. Whereas the mucosa of normal paranasal sinuses has relatively few glands, inflamed sinus mucosa contains more developed and pathological mucous glands.⁴

MICROBIOLOGY

Acute viral upper respiratory infections are the most frequent cause of acute sinus inflammation.^{4–6} Organisms commonly causing acute bacterial sinusitis include *Streptococcus pneumoniae*, *Hemophilus influenzae*, and *Moraxella catarrhalis*. Polysaccharide coatings typical of these bacteria impair phagocytosis. In addition, many of these bacteria secrete molecules that interfere with mucociliary clearance.²⁴ The most common bacterial species isolated in chronic sinusitis, in addition to those just mentioned, are *Staphylococcus aureus*, Gram-negative enteric organisms (including *Pseudomonas aeruginosa*), and anaerobes, such as *Prevotella* spp. and fusobacteria. However, the role of infection in most patients with chronic sinusitis is controversial and the microbiology results may just reflect colonization.⁴ Fungal sinusitis has been traditionally divided into four primary categories: acute infectious/fulminant (invasive); chronic/indolent (invasive); fungus ball (noninvasive); and allergic. In addition, it has been proposed that noninvasive fungal colonization of the upper airway is an underlying cause of chronic sinusitis, although this is controversial.^{25,26}

Fig. 41.3 Anatomy of sinuses with normal ostiomeatal complex. Coronal noncontrast CT scan demonstrates the ostiomeatal complex. Normal mucociliary drainage is from the maxillary sinus up through the infundibulum (i) and maxillary sinus ostium into the middle meatus (m). The ethmoid bulla (e) and uncinate process (u) form the lateral and medial walls of the infundibulum, respectively. A normal anatomic variant of a Haller air cell (H) underlying the orbit causes a mild narrowing of the left infundibulum. A smaller Haller cell is present on the right. The mild asymmetry of the mucosa of the inferior turbinates (it) and middle turbinates is part of the normal nasal cycle. (Modified from Cummings CW, Flint PW, Haughey BH, et al. *Otolaryngology head and neck surgery*, 4th edn. Philadelphia: Elsevier, 2005; 80.)

FACTORS INCREASING RISK FOR SINUSITIS

Many factors have been reported to predispose to sinusitis, although the level of evidence that supports such causal associations varies greatly for different factors. Reported factors include viral upper respiratory tract infections, rhinitis (allergic and non allergic), anatomical abnormalities (foreign body, nasal polyps, nasal septal deviation, enlarged tonsils and adenoids, concha bullosa and other middle turbinate abnormalities), tumors, trauma (physical, chemical, or barotrauma), cystic fibrosis, antibody deficiency, acquired immunodeficiency syndrome, ciliary dyskinesia, Kartagener's syndrome, Young's syndrome, systemic diseases (e.g., Churg–Strauss syndrome, Wegener's granulomatosis), and dental infection.^{4–6} More important factors are thought to be obstruction of the sinus ostia, impaired ciliary function, and impaired host immunity (especially antibody deficiency).^{4,5} Mucosal edema, as may occur from rhinitis or anatomic abnormalities (e.g., nasal polyps, septal deviation) that obstruct drainage from or ventilation of sinuses, promotes mucus accumulation in the sinuses, serum transudation, and decreased oxygenation within the sinuses.⁴ These changes result in impaired ciliary movement of mucus and promotion of bacterial growth. More recently, gastroesophageal reflux disease (GERD) has been suggested as a cause of sinusitis, and several studies report that medical treatment of GERD results in improvement in sinusitis symptoms.⁴

ACUTE SINUSITIS

Most cases of infectious rhinosinusitis of less than 7–10 days' duration are viral.^{4,5,27,28} Acute bacterial sinusitis in adults most often presents with 7 days of symptoms of purulent anterior rhinorrhea, nasal congestion, postnasal drip, facial or dental pain/pressure, and/or cough, often worse at night. Children with acute sinusitis most commonly have cough and rhinorrhea.^{4,28} In all age groups with acute sinusitis, less frequent symptoms may include fever, nausea, fatigue, anosmia, and halitosis. Occasionally, fungal infections can cause acute sinusitis. These are more likely to occur in diabetes mellitus and immunocompromised states.⁴

CHRONIC SINUSITIS

Historically it was thought that chronic rhinosinusitis evolved as a consequence of untreated acute bacterial sinusitis. However, linear progression from acute to chronic bacterial rhinosinusitis has not been established. In addition, the view that chronic sinusitis is primarily an infectious process is no longer held.^{4–6} Instead, current data indicate that active infection may only be present in a minority of patients with chronic sinusitis, and that other patients have inflammation sustained by other processes.^{4–6} Broadly, chronic sinusitis can be classified as either infectious or inflammatory (noninfectious). The following discussion reviews the principal concepts of chronic sinusitis but pertains primarily to data from adults. Because the sinus mucosa of young children with chronic sinusitis has less eosinophilic inflammation, basement membrane thickening, and mucus gland hyperplasia than in adult chronic sinusitis,²⁹ studies of chronic sinusitis in adults may not be fully applicable to chronic sinusitis in children.

Chronic infectious sinusitis

Bacterial chronic sinusitis can be associated with a variety of organisms, as discussed under Microbiology above. Chronic infectious sinusitis is generally associated with a significant influx of neutrophils, and is more likely to occur in patients with underlying humoral immune deficiencies, AIDS, cystic fibrosis, or Kartagener's syndrome.⁴ More recently, bacterial biofilms have been proposed to be important in promoting chronic sinus infection. Biofilms are complex aggregations of interacting bacteria attached to a surface that are encased in a protective matrix of polysaccharides.³⁰ This encasement protects the bacterial community from antibiotic penetration and the host's natural defenses, potentially leading to refractory infections. As with acute fungal sinusitis, chronic infectious fungal sinusitis is more common in diabetes mellitus and immunocompromised states, and in geographic areas with high humidity.

Chronic inflammatory sinusitis

Chronic hyperplastic (hypertrophic) eosinophilic sinusitis (CHES)

This noninfectious form of CS is characterized by mucosal hyperplasia with a preponderance of eosinophils and mixed mononuclear cells with relatively few neutrophils. Frequently associated with nasal polyps, asthma and aspirin sensitivity, it often responds poorly to therapy.^{4,6} Th2 lymphocytes appear to play an important role in initiating CHES.

Fig. 41.4 Chronic hyperplastic eosinophilic sinusitis (CHES): part of a systemic disease of the airways. Although this figure depicts a theorized allergen-induced pathway that leads to CHES and asthma, any number of putative stimuli (see text) might initiate an analogous cascade of events driven by Th2-like lymphocytes. Here, allergen exposure activates immune cells, including Th2 lymphocytes, dendritic cells, mononuclear phagocytic cells, and mast cells within the nares and in nasal-associated lymphatic tissues. These cells might also include locally produced CD34⁺ IL-5Ra⁺ eosinophil-basophil (Eo/B) progenitors. It is presumed that the newly activated Th lymphocytes will have the phenotype of Th2-like cells characterized by their production of IL-3, IL-4, IL-5, IL-9, IL-13, eotaxin (CCL11), and GM-CSF. Such cells can migrate to the bone marrow, where they stimulate the production of inflammatory cells, including basophils, mast cells, and, most importantly, eosinophils. These newly generated inflammatory cells enter the circulatory system, from which they are selectively recruited via specific adhesion molecules (e.g., VCAM-1) and chemoattractants (e.g., eotaxin) back to the nose, but also to the lungs and sinuses, exacerbating inflammation. (From Borish L. Allergic rhinitis: Systemic inflammation and implications for management. *J Allergy Clin Immunol* 2003; 112: 1024 with permission from Elsevier.)

Current research is defining the role of numerous putative stimuli, including allergens, bacteria, bacteria-derived superantigens (e.g., staphylococcal enterotoxins), osteitis, biofilms, and fungal derived antigens.^{4, 6, 21, 22, 26–28, 30–32} It has also been proposed that, once initiated, cellular differentiation pathways could lead to the development of an antigen-independent permanent process²⁷ (Fig. 41.4).

Both in the aspirin-sensitive and -tolerant patients, the disease severity of CHES and eosinophilic infiltration correlates with increased leukotriene C₄ synthase and 5-lipoxygenase activity and increased levels of cysteinyl leukotriene production.⁴ The mechanism of aspirin-sensitive

disease has been proposed to involve abnormal arachidonic acid metabolism, an increased absolute number of cells expressing the CysLT₁ receptor, and decreased expression of certain prostanoid receptors for PGE₂, with consequent impaired braking of inflammatory cell cysteinyl leukotriene production by PGE₂.^{33–35} Because there is greater expression of cysLT₂ than cysLT₁ receptors on epithelial and glandular cells, the effects of cysteinyl leukotrienes on mucosal glands and epithelium in rhinosinusitis may be mediated predominantly through cysLT₂.³⁶

In CHES with nasal polyps (but not CHES without nasal polyps) there is a significantly increased prevalence of *Staphylococcus aureus*

colonization.³⁷ These bacteria release enterotoxins which act as superantigens and induce topical multiclonal IgE formation, as well as a severe, possibly steroid-insensitive eosinophilic inflammation. The presence of IgE antibodies in nasal polyps is only partially related to the serum IgE and skin-prick results. Polyp specimens show follicular structures with B and T cells and diffuse lymphoid accumulations with plasma cell infiltration.³⁷

Overall, studies suggest that increased production of IL-5 is likely to influence the predominance and activation of eosinophils in nasal polyps, independent of atopy.³⁷ However, the development of eosinophilic nasal polyps may not be simply explained as a Th2-driven process, as both Th1- and Th2-type cytokines are upregulated in eosinophilic nasal polyps, in patients with and without positive allergen skin tests.³⁸

Allergic fungal sinusitis (AFS)

AFS is a distinct entity that has traditionally been viewed as the most common form of fungal sinusitis. It occurs in immunocompetent patients and results from a hypersensitivity response to saprophytic fungi such as *Aspergillus* spp. that colonize the sinuses.³⁹ More prevalent in certain geographic areas, AFS is often associated with nasal polyps and asthma. Typical diagnostic features include CT or MRI evidence of sinusitis, 'allergic mucin' in the sinuses (dark green or black material with the consistency of peanut butter that typically contains a few hyphae and Charcot-Leyden crystals), a positive skin test to the relevant organism, and elevated total serum IgE.⁴ Treatment involves surgical exenteration and steroid therapy.

Chronic noneosinophilic sinusitis

A predominantly neutrophilic inflammatory response in chronic sinusitis is generally associated with an infectious process. In contrast to chronic sinusitis associated with eosinophilic infiltrates, nasal polyps occur less commonly, except in patients with cystic fibrosis in whom nasal polyps with predominantly neutrophilic infiltrates are frequent.⁴ Other patients with chronic sinusitis can have inflammatory infiltrates characterized more by lymphocytes and mononuclear phagocytes. Although these latter patients have been thought to have chronic or recurrent sinus occlusion underlying their disease, the factors that drive differential inflammatory infiltrates in chronic sinusitis are not fully understood.

Nasal polyps

Frequently associated with sinus disease, nasal polyps are benign inflammatory growths that arise from the inflamed mucosa lining the paranasal sinuses. They may cause invariant nasal obstruction and loss of smell or rhinorrhea. The presence of nasal polyps in children is uncommon, and merits testing for cystic fibrosis.⁴ Neutrophils are more characteristic of nasal polyps associated with cystic fibrosis, whereas, as discussed above, eosinophilic infiltrates are more typical of polyps associated with CHES, aspirin sensitivity and asthma. Although it had generally been assumed that allergy is a cause of nasal polyps, the prevalence of nasal polyposis in allergic patients is typically less than 5%, and the prevalence of documented allergy is not increased in patients with nasal polyps.^{1,4,40} Corticosteroids are an effective medical treatment, although surgical polypectomy may be required.

RELATIONSHIP BETWEEN SINUSITIS AND ASTHMA

Although data relating sinus disease to asthma are far less extensive than those relating rhinitis to asthma, the relationship is conceptually analogous. In a CT study, paranasal sinus abnormalities were shown in nearly all patients with moderate to severe asthma.⁴¹ Evidence of eosinophilia in the sinus mucosa is stronger in patients with rhinosinusitis and asthma, as opposed to rhinosinusitis alone.¹ Medical and surgical treatment of sinus disease appears to have beneficial effects on asthma outcomes, but the studies reporting such findings typically have not been randomized and the outcomes are frequently subjective.^{1,4}

DIAGNOSIS OF SINUSITIS

History

Acute bacterial sinusitis (ABS)

The principal issue in clinical practice is differentiating between an acute viral upper respiratory infection (URI) and acute bacterial sinusitis (ABS). Most viral URIs last 5–10 days, with a peak in nasal symptoms and/or cough by days 3–6 and subsequent improvement and resolution of constitutional symptoms such as fever, headache and myalgia within the first few days of illness.^{4,42} Although nasal discharge begins as clear and watery, it often becomes thicker, mucoid and even purulent for several days before reversing its appearance and then drying. ABS may have several presentations. The most common ABS presentation is onset of nasal symptoms (anterior or posterior nasal drainage, congestion) and/or cough that does not improve beyond 7–10 days. ABS may also present with severe symptoms including a fever = 38.5° that persists for at least 3–4 days (longer than expected in a viral URI) with nasal discharge, and in adults, facial pain. A third presentation of ABS is a biphasic course in which a patient begins with URI-type symptoms that appears to be resolving, followed by significant worsening of nasal symptoms and/or cough with new or recurrent fever at about 1 week into the illness.

Chronic sinusitis

Chronic rhinosinusitis may cause symptoms that persist for months to years and may be less severe than those of acute rhinosinusitis. Nasal obstruction or posterior discharge are usually the chief complaints of chronic rhinosinusitis, making it difficult to distinguish this condition from rhinitis without sinusitis. Chronic cough (especially during the night, or upon waking in the morning) is also a common presenting symptom of chronic rhinosinusitis.^{4-6,43} Clinical evidence of sinusitis occasionally may be subtle, except during acute purulent episodes.

Physical examination

Typical physical signs include nasal mucosal edema, sinus tenderness (albeit neither a sensitive nor a specific finding), and purulent nasal secretions. However, purulent nasal secretions do not necessarily indicate an infectious process, let alone bacterial sinusitis.⁴⁻⁶ The nose should be examined for deviated septum, nasal polyps, foreign bodies, and tumors. Maxillary sinusitis is suggested by sensitivity of the

maxillary teeth. The ears and chest should be examined for signs of associated otitis media and asthma.¹

Nasal endoscopy/rhinology

Nasal endoscopy offers a significantly better visualization of the nose than a nasal speculum. The origin and extent of nasal polyps, other anatomic abnormalities and the presence of purulent ostial secretions may be identified.

Imaging studies

In routine cases of suspected acute bacterial rhinosinusitis, imaging studies are not required and may even be misleading.³⁻⁵ Up to 40% of sinus radiographs and more than 80% of CT scans may be abnormal in viral rhinosinusitis if obtained within 7 days of the onset of illness.⁴² However, imaging studies become appropriate when there is an incomplete response to initial management, or chronic sinusitis is suspected. Occipitomeatal view radiographs may be helpful in screening adults and children over 1 year of age, but have inadequate sensitivity.

CT scans of the sinuses can identify disease not demonstrated by standard radiographs, and are of particular value in assessing obstruction of the sinus ostia. Radiographic signs consistent with acute sinusitis include maxillary sinus findings of either mucosal thickening >6 mm in adults (>4 mm in children), or >33% loss of air space volume, or opacification or air/fluid levels in any paranasal sinus.^{4,6} A limited four- to five-image coronal sinus CT scan, with a focus on the ostiomeatal complex, may be helpful and should be considered if imaging is deemed necessary.⁴ A complete series sinus CT scan fully defines sinus anatomy and is mandatory before surgery. Suspected orbital involvement is best identified by axial views. In allergic fungal sinusitis, CT scans demonstrate a characteristic heterogeneous appearance within the involved paranasal sinuses (Fig. 41.5).

MRI does not distinguish air from bone. Because examination of the air-bone interface is important in the evaluation of anatomic defects, MRI is not used for routine evaluation of suspected sinusitis. However, it may be of great value when fungal sinusitis and tumors are suspected. Fungal sinus disease is associated with a characteristic hypointense signal on T₂-weighted scans.

Transillumination is not reliable in diagnosing sinusitis.^{4,5}

Bacterial cultures and other laboratory studies

The overall presentation of history and physical findings is usually sufficient to make the diagnosis of acute, uncomplicated sinusitis. Diagnostic testing becomes important when initial therapy fails, or when symptoms are chronic or recurrent.^{4,5} Nasal cultures are not reliable for establishing the diagnosis of sinusitis, or for determining a specific causative microorganism.⁴ Maxillary antrum tap with aspiration for culture is definitive in adults, but is invasive, may be uncomfortable, and is indicated only when precise microbial identification is essential.⁴ Obtaining cultures of the middle meatus through endoscopically directed culture has shown promise in adults, but not in children.^{4,45}

If present, the identification of large numbers of neutrophils in nasal secretions by nasal cytology can help distinguish between infectious sinusitis and rhinitis.⁴

When patients present with recurrent or chronic sinusitis and infections of the lower respiratory tract, testing for immunodeficiency should

be considered, including quantitative immunoglobulins, functional antibody tests, and HIV testing.

Quantitative sweat chloride tests and genetic testing for diagnosis of cystic fibrosis should be considered in children with nasal polyps and/or colonization of the nose and sinuses with *Pseudomonas* species and who developed chronic sinusitis at an early age.

THERAPEUTIC PRINCIPLES

ACUTE SINUSITIS

Findings in acute sinusitis that suggest complications and a possible need for immediate referral to a specialist include:

- >> Facial swelling/erythema over an involved sinus
- >> Visual changes; abnormal extraocular movements; proptosis; periorbital edema or erythema
- >> Neurologic signs that suggest intracranial or central nervous system involvement
- >> Severe headaches and high fevers

Fig. 41.5 Soft tissue algorithm CT showing findings typical of AFRS. Note heterogeneous appearance within involved paranasal sinuses. (From Meltzer EO, Hamilos DL, Hadley JA et al. Rhinosinusitis: establishing definitions for clinical research and patient care. *J Allergy Clin Immunol* 2004; 114: 170 with permission from Elsevier.)

Differential considerations

The differential diagnosis of sinusitis includes acute viral upper respiratory infections, various forms of rhinitis, nasal polyps, Horner's syndrome, Wegener's granulomatosis/midline granuloma, Churg–Strauss vasculitis, trauma, enlarged tonsils and adenoids, tumors, dental infections, cerebral spinal fluid (CSF) rhinorrhea, and migraine or tension headaches.^{4–6} Findings on history and physical examination should direct further testing, which may include allergy testing, and other diagnostic procedures (Fig. 41.6). Although headache can be a feature, particularly in acute sinusitis, over 90% of self- and physician-diagnosed sinus headaches meet the International Headache Society criteria for migraines. Accordingly, most cases of 'sinus headache' are not in fact due to sinus disease.^{46, 47}

TREATMENT

Acute sinusitis

Antibiotics

When symptoms suggestive of rhinosinusitis persist beyond approximately 7 days, bacterial rhinosinusitis becomes more likely. In an effort to promote judicious use of antibiotics, several guidelines recommend

a 7–10-day period of watchful waiting for spontaneous resolution of symptoms before prescribing antibiotics.^{4, 27, 28} In such cases, antibiotic usage is appropriate when moderate to severe symptoms are present, although most cases of milder acute bacterial rhinosinusitis will resolve without the need to prescribe antibiotics. However, some guidelines also recommend that antibiotics be considered regardless of the duration of illness when severe signs or symptoms of sinusitis are present: temperature $>39^{\circ}\text{C}$, maxillary tooth or facial pain (especially when unilateral), unilateral sinus tenderness, periorbital swelling, or worsening symptoms after 3–5 days.^{4, 5} A 10–14-day antibiotic course is typically prescribed for acute sinusitis, although a shorter course may be adequate with certain newer antibiotics. The choice of antibiotic should consider cost, safety, and changing local patterns of bacterial resistance.⁴ Accordingly, it is not possible to make a universally applicable recommendation for first-line agents. In many geographic areas amoxicillin is a reasonable first-line antibiotic, although surveillance studies indicate the development of significant pneumococcal resistance due to alteration of penicillin-binding proteins,⁴ and there is a high frequency of β -lactamase-positive *H. influenzae* and *M. catarrhalis*.⁴ In some areas, trimethoprim-sulfamethoxazole can be used as an alternative in adults, although bacterial resistance is higher in children.⁴ The macrolides clarithromycin and azithromycin have extended coverage and are effective against β -lactamase-producing organisms. Other antibiotics with broader coverage include amoxicillin/clavulanate, some second- or third-generation cephalosporins (e.g., cefuroxime, cefpodoxime, cefprozil), and for adults, quinolones. First-generation cephalosporins such as cephalexin have poor *H. influenzae* coverage, whereas certain second-generation cephalosporins (e.g., cefaclor) have become less useful as *H. influenzae* and *M. catarrhalis* have become increasingly resistant to them.

When a patient fails to improve significantly after approximately 5 days' treatment, or there is a high prevalence of β -lactamase resistance, antibiotics with broader coverage should be prescribed.

Other therapies

In clinical practice, bacterial sinusitis is treated not only with antibiotics, but also with adjunctive agents and approaches such as analgesics, adequate hydration, steam inhalation, and pharmacologic measures intended to treat pathologic factors associated with sinusitis (e.g., underlying rhinitis, impaired ostial patency). Such pharmacologic measures include topical steroids, oral steroids, oral antihistamine in allergic patients, nasal saline, nasal douches/irrigation, topical and oral decongestants, and mucolytics.^{4, 5} However, the use of many agents commonly prescribed for sinusitis is not based on firm evidence.^{4, 5} Moreover, even when there is evidence that a pharmacologic intervention improves clinically meaningful symptoms of rhinosinusitis in controlled trials, critical analysis can question whether the improvement occurs because of effects on the rhinitis component, rather than directly improving bacterial sinus infection per se. For example, there are controlled studies in acute rhinosinusitis demonstrating that nasal steroids can decrease associated nasal symptoms, headache, facial pain, and cough after several weeks of treatment.^{4, 5} However, it is argued that these endpoints may reflect the known effects of nasal steroids on rhinitis, and that other endpoints, such as greater or more rapid resolution of positive bacterial sinus cultures, would be required to demonstrate efficacy in bacterial sinusitis.⁴⁸

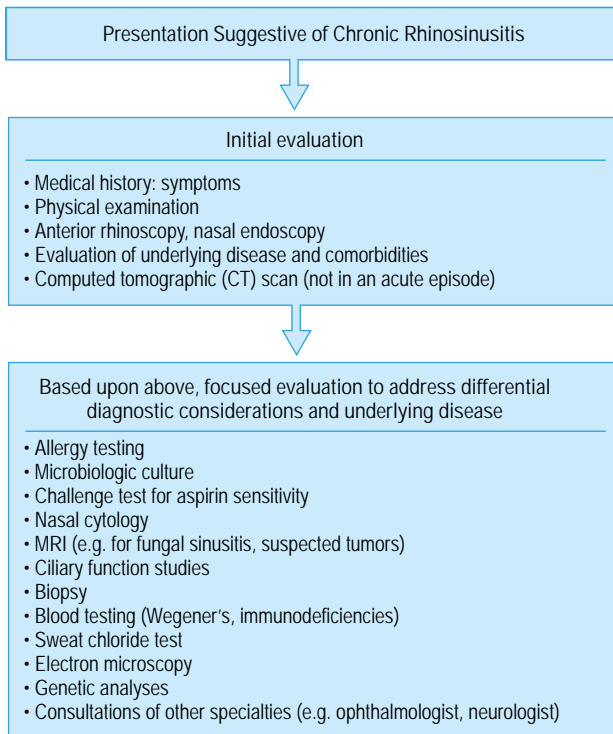

Fig. 41.6 Diagnostic approach to suspected chronic rhinosinusitis. (Adapted from Adkinson NF Jr, Yunginger JW, Busse WW, et al. Middletons allergy principles and practice, 6th edn. Philadelphia: Mosby, 2003; 78 with permission from Elsevier.)

When therapy fails

If the response to medical intervention is still inadequate, a sinus CT scan is indicated to confirm the presence of sinusitis and determine whether anatomic abnormalities may be predisposing to the problem. Specialist evaluation is appropriate when sinusitis is recurrent or refractory to treatment. Surgical intervention may be required in acute sinusitis to provide drainage when there is a significant risk of intracranial complications, or in patients with periorbital or intraorbital abscess or visual compromise.

Chronic sinusitis

Medical therapy

Guidelines recommend that chronic sinusitis should be treated with antibiotics for prolonged courses (at least 3 weeks; up to 3 months), although there is a relative paucity of controlled trials.⁴⁻⁶ Most adjunctive agents commonly used for acute sinusitis are also commonly used for chronic sinusitis, but there is generally even less evidence in controlled trials of their efficacy. In addition, it has been proposed (but not yet convincingly proven) that other medical treatments may be useful in chronic sinusitis, including systemic and topical antimycotics, leukotriene modifiers, and proton pump inhibitors (in patients in whom gastric reflux is suspected to play a role).^{4,5} Because chronic sinusitis is associated with AR in 40–80% of adults and 36–60% of children, some guidelines recommend that patients with chronic sinusitis be evaluated for allergy so that environmental control measures for allergic disease can be implemented.⁴ In patients with aspirin sensitivity and hyperplastic sinus disease, aspirin desensitization has been reported to improve long-term outcomes.⁴⁹ During treatment of chronic sinusitis, but particularly if initial measures fail, there should be consideration of all factors that may be promoting chronic disease which may direct further interventions (Fig. 41.6).

Surgical therapy

Referral for surgical intervention should be considered if sinusitis does not respond to medical intervention. Functional endoscopic sinus surgery (FESS) has generally supplanted older surgical techniques.⁵⁰ FESS is typically directed at the removal of locally diseased ethmoid tissue (important in the development of frontal and maxillary sinusitis) to improve ventilation and drainage of larger, dependent sinuses.

Urticaria, angioedema, and anaphylaxis

Elena Borzova, Clive E.H. Grattan

42

Urticaria is a common skin disorder that can lead to severe impairment of quality of life. Recently, there has been substantial progress in our knowledge and understanding of the pathophysiology of the condition, offering new diagnostic and treatment approaches for at least some patients. However, in many cases, urticaria is still a disease of unknown etiology that is difficult to manage effectively.

DEFINITION

Urticaria is a heterogeneous group of disorders that share a distinct skin reaction pattern, i.e., the development of urticarial skin lesions.¹ Urticarial lesions resulting from localized edema of the upper dermis are called wheals (Fig. 42.1), whereas pronounced swelling of deeper dermal layers, subcutis, and submucosal tissues is known as angioedema (Fig. 42.2).

EPIDEMIOLOGY

Urticaria is common: up to 25% of the general population experience some form of urticaria at least once over their lifetime, whereas the lifetime prevalence of chronic urticaria (CU) is between 0.1% and 3% of the general population.^{2,3} Acute urticaria affects mainly young adults with an obvious female preponderance,³ whereas CU is more common in adults, affecting mainly middle-aged women, and is rare in children and adolescents.²⁻⁴ By definition, acute urticaria resolves within 6 weeks, whereas CU lasts on average 3–5 years. Rarely, CU may last for > 10 years. However, CU is almost always a self-limiting disorder, resolving spontaneously in 50% patients within 6 months of onset.⁴

GENETICS

With the exception of hereditary angioedema and the hereditary auto-inflammatory periodic syndromes, urticaria does not show mendelian inheritance. Nevertheless, there is some evidence of genetic predisposition and human leukocyte antigen (HLA) associations in CU.⁵⁻⁸

Although earlier studies found no association between HLA class I antigens and CU, a recent study showed an increased frequency of HLA-Bw4 in CU.⁵ Several associations have been reported for class II HLA antigens in CU in different ethnic populations. A link between CU and HLA DRB1*04 (DR4) and its associated allele, DQB1*0302 (DQ8), was described in British CU patients compared with a control population. This link with the HLA DR4 haplotype was also confirmed in Turkish CU patients,⁷ while strong associations with HLA-DRB1*1302 and DQB1*0609 alleles were found for aspirin-induced urticaria in Korean patients.⁸

KEY CONCEPTS

DEFINITION OF URTICARIA

- >> Urticaria is characterized by superficial and deep swellings
- >> Wheals are superficial swellings of the dermis of skin: they are pale and itchy with surrounding redness when they appear and then go pink before fading
- >> Angioedema is a deep swelling below the skin or mucosa that usually lasts longer than wheals and may be painful rather than itchy
- >> Wheals may occur alone or together with angioedema in urticaria
- >> Acute urticaria lasts less than 6 weeks. It is common and often caused by viral infections. Urticaria due to drugs and foods falls in this category, but the diagnosis is usually clear from the history
- >> Chronic urticaria lasts 6 weeks or more with continuous disease activity. A cause may not be found. Urticaria occurring intermittently over a period of more than 6 weeks can be defined as episodic
- >> When angioedema occurs without wheals, C1 esterase inhibitor deficiency should be excluded

Fig. 42.1 Spontaneous wheals in severe ordinary urticaria showing superficial pink swellings with pale edematous centers.

CLINICAL PATTERNS

Urticaria is often classified by the duration of continuous activity into acute (less than 6 weeks), chronic (6 weeks or more), or episodic, where short episodes occur repeatedly over a period of time. This classification has the merit of simplicity but takes no account of etiology or clinical features that may help clinical management or research. Classification of urticaria by etiology is satisfying academically but of little value in the clinic, where the etiology is often unknown and management decisions have to be based solely on the clinical assessment.⁹

ETIOPATHOGENESIS AND ETIOLOGICAL CLASSIFICATION

Although many aspects of the pathophysiology of urticaria remain unclear, our understanding has advanced considerably over the last two decades, allowing an etiological classification (Table 42.1).

MAST CELL-DEPENDENT MECHANISMS

Skin mast cells are key players in the pathogenesis of urticaria. They are predominantly located around the small blood and lymphatic vessels as well as around or within peripheral nerves.³ Mast cell population density is greatest at distal body areas, including the face, hands, and feet.¹⁰ There is conflicting evidence as to whether the number of cutaneous mast cells in urticaria patients is increased but there is general agreement that they release mediators more readily than normal.

Human skin mast cells contain preformed mediators in their granules, including histamine, proteases (tryptase, chymase), and heparin. They express many membrane receptors, including high-affinity immunoglobulin E (IgE) and low-affinity IgG receptors. Unlike mast cells elsewhere (pulmonary and intestinal), skin mast cells possess complement C5a receptors and activation sites for neuropeptides and basic secretagogues.⁴

Fig. 42.2 Angioedema of the mouth in C1 esterase inhibitor deficiency.

Skin mast cell activation is central to the pathophysiology of CU. Mast cells can be activated by a variety of immunological and nonimmunological triggers (Fig. 42.3).¹¹ Immunological and nonimmunological pathways of mast cell activation are characterized by distinct patterns of mediator release. Immunological activation of mast cells requires prior sensitization and is triggered by cross-linking of high-affinity IgE receptors (FcεRI) by antigen bound to antigen-specific IgE, by anti-FcεRIα, or by anti-IgE antibodies. Histamine release peaks at 5–10 minutes, followed by *de novo* synthesis of lipid-derived mediators (leukotriene C4 and prostaglandin D₂) and cytokines.¹² In contrast, nonimmunological stimulation of mast cells by neuropeptides, opiates, compound 48/80, or C5a leads to rapid histamine release within 15–20 seconds, without generation of eicosanoids and cytokines.¹² Moreover, prolonged and subthreshold immunological stimulation may result in a state of receptor desensitization. For example, desensitization of FcεRI may lead to basophil hyporesponsiveness to anti-IgE in autoimmune CU.¹³ However, the desensitization of receptors by immunological stimulation does not affect nonimmunological release. Interestingly, enhanced responsiveness of skin mast cells to some nonimmunological stimuli has been observed in patients with CU.

Allergic urticaria

Immunological triggers of mast cell activation play an important role in different types of urticaria.^{3, 11} The classical example of immunological mast cell activation via high-affinity IgE receptors is IgE-mediated urticaria (often termed allergic urticaria). In allergic urticaria, the cross-linking of receptor-bound IgE leads to the release of diverse preformed mediators and newly synthesized lipid mediators and cytokines, resulting in the early and late-phase IgE-mediated allergic inflammatory responses.

IgE-mediated mast cell activation usually presents as acute allergic urticaria in sensitized individuals and is very rarely, if ever, responsible for chronic whealing. Examples include some food- and drug-induced urticarias and latex-induced contact urticaria. Allergic urticaria to inhaled allergens (e.g., latex, animal epithelia) is often accompanied by respiratory symptoms. Generalized allergic urticaria may progress to anaphylaxis.

Table 42.1 Clinical patterns of urticaria

Ordinary urticaria

Acute
Chronic
Episodic

Physical urticaria

Mechanical: dermatographism, delayed-pressure urticaria, vibratory angioedema
Thermal: cold-induced urticaria, localized heat-induced urticaria
Cholinergic urticaria and pruritus
Aquagenic urticaria and pruritus
Solar urticaria
Exercise (and food) induced anaphylaxis

Contact urticaria
Angioedema without wheals

Angioedema, due to C1 inhibitor deficiency
Angioedema with normal C1 inhibitor

Urticarial vasculitis

Normocomplementemic urticarial vasculitis
Hypocomplementemic urticarial vasculitis

Autoinflammatory syndromes (presenting with urticaria)
Hereditary (cryopyrin-associated) periodic syndromes

Familial cold autoinflammatory syndrome
Muckle-Wells syndrome
Chronic infantile neurological cutaneous and articular syndrome

Acquired

Schnitzler's syndrome

Allergic urticaria resolves rapidly on withdrawal of allergen exposure and recurs with each re-exposure to the allergen or cross-reactive agents.

Autoimmune urticaria

Autoimmune urticaria is mediated by histamine-releasing autoantibodies directed against the extracellular α -chain of Fc ϵ RI on dermal mast cells or basophils or, less frequently, against receptor-bound IgE. These functional autoantibodies have been demonstrated by several independent research groups in 25–50% of adult and pediatric patients with the ordinary presentation of CU.^{13, 14} The pathophysiology of autoimmune CU involves cross-linking of high-affinity IgE receptors by autoantibodies leading to degranulation of mast cells and basophils. There is good evidence that activation of cutaneous mast cells by IgG derived from CU sera *in vitro* is dependent on C5a but not all histamine-releasing IgG derived from CU sera are complement-dependent on basophil assays. Most functional autoantibodies are IgG₁ or IgG₃,¹⁴ which are known to fix complement. By contrast, nonfunctional anti-Fc ϵ RI autoantibodies demonstrated by Western blot or enzyme-linked immunosorbent assay (ELISA) in other autoimmune diseases (including systemic lupus erythematosus and bullous pemphigoid) are generally from the noncomplement-fixing subclasses IgG₂ and IgG₄.¹⁴

Fig. 42.3 Schematic representation of a mast cell or basophil illustrating activation of the immunoglobulin E (IgE) receptor by cross-linking with immunological stimuli (allergen/specific IgE binding, anti-IgE, or anti-Fc ϵ RI autoantibodies) or independent activation by nonimmunological stimuli (substance P, stem cell factor, codeine, or C5a) leading to degranulation.

Recently, anti-CD23 antibodies have also been detected in CU patients.¹⁵ The low-affinity IgE receptor Fc ϵ RII/CD23 expressed on B lymphocytes and eosinophils may therefore be another target antigen for an autoimmune response in CU. The interaction between anti-CD23 antibodies and CD23 on eosinophils may induce release of major basic protein 1 (MBP-1), a potent IgE-independent histamine-releasing agent, resulting in activation of mast cells and basophils. The clinical relevance of anti-CD23 antibodies in CU remains to be elucidated but they may play a role in CU patients without autoantibodies against Fc ϵ RI or IgE.

Immune complex-mediated urticaria

Mast cell activation can result from binding of circulating immune complexes to Fc ϵ RIII, expressed on mast cells.^{3, 11} In addition, circulating immune complexes can activate complement, leading to C3a and C5a anaphylatoxin formation. Urticaria caused by immune complexes may occur in serum sickness-like reactions, transfusion reactions, some drug-induced urticarias, and urticaria associated with infectious or autoimmune diseases. Immune complex-mediated urticaria usually develops 1–3 weeks after initial exposure to the antigen and disappears several weeks after antigen discontinuation. Chronic immune complex-mediated urticaria is known as urticarial vasculitis (UV; see below). In this condition, urticaria may be associated with systemic symptoms, such as fever, arthritis, or nephritis. Damage to postcapillary venules results from the deposition of immune complexes in the vessel wall. Immune complexes are formed on exposure to external (drug or infections) or internal (collagen-like region of C1q) antigens. Complement activation via the classical pathway leads to neutrophil chemotaxis through cytokine expression and adhesion molecule activation (Fig. 42.4). Proteolytic enzymes released from neutrophils damage vessel walls, leading to wheal formation and red blood cell extravasation.

Fig. 42.4 Immune complex-mediated urticaria initiated by lodging of antigenic complexes in small blood vessels followed by C3a and C5a generation resulting in mast cell degranulation and cytokine upregulation of adhesion molecules (ICAM-1, E-selectin) by tumor necrosis factor- α (TNF- α) and interleukin-8 (IL-8), leading to tissue recruitment of neutrophils and eosinophils and activation of tissue plasminogen activator (t-PA).

Nonimmunological mast cell activation

Skin mast cells can be activated nonimmunologically by many agents, including neuropeptides (substance P, neuropeptide Y, vasoactive intestinal peptide, or somatostatin), calcitonin gene-related protein, compound 48/80, and natural polyamines.^{3,11,12} Drugs (e.g., opiates, muscle relaxants, radiocontrast media, polymyxin B) may also cause dose-dependent non-immunological urticaria by activating membrane-associated G-coupled proteins. A classical clinical example is codeine-induced acute urticaria.

Mast cell and basophil releasability in urticaria

Besides the nature of the stimulus, the clinical signs of urticaria also depend on the releasability of effector mast cells in urticaria. In CU patients, dermal mast cells show a decreased activation threshold. Although CU basophils are hyporesponsive to immunological stimuli such as anti-IgE, they are paradoxically hyperresponsive to an as-yet unidentified factor in normal human serum.¹⁴

Skin response to mast cell activation in chronic urticaria

Despite there being different pathways for mast cell activation, the end result is degranulation with release or secretion of mediators. Histamine is crucial for the development of cutaneous manifestations of urticaria and is found in high concentrations in tissue fluid of wheals. It causes localized redness due to vasodilatation, wheal formation resulting from increased vascular permeability and edema, and a surrounding axon reflex-mediated flare. Histamine is also the main, if not the only, mediator of pruritus in urticaria. However, wheals caused by histamine alone

are short-lived whereas urticarial lesions may persist up to 24 hours, implying that other proinflammatory mediators must also contribute.

MAST CELL-INDEPENDENT MECHANISMS OF URTICARIA

Pseudoallergy

Pseudoallergy or nonallergic hypersensitivity clinically mimics immediate-type allergic reactions without any evidence of underlying immunological mechanisms.¹⁶ The most common triggers of pseudoallergic reactions are aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) as well as some food ingredients and additives such as salicylates, benzoates, and tartrazine.¹⁶ These reactions do not involve sensitization and can, therefore, occur on first exposure to the culprit agent. Pseudoallergic reactions are dose-dependent and usually occur with chemically unrelated substances. The diagnosis is difficult because skin tests and serology are irrelevant. Diagnosis of nonallergic hypersensitivity is based on a distinctive clinical pattern, time course, clinical signs, and response on elimination of the cause. In the appropriate clinical context, pseudoallergy can be confirmed with oral challenge tests.

NSAIDs

Aspirin and other NSAIDs inhibit constitutive cyclooxygenase (COX-1) and inducible cyclooxygenase (COX-2), thereby diverting arachidonic acid metabolism towards the 5-lipoxygenase pathway in some cell types, notably eosinophils. This modulation of arachidonic acid metabolism results in overproduction of cysteinyl-leukotrienes LTC₄, D₄, and E₄, leading to vasodilatation and edema. Furthermore, reduction of

Fig. 42.5 Arachidonic acid pathways illustrating potential diversion from prostaglandin synthesis to cysteinyl leukotrienes (LTC₄, D₄, E₄) by blocking cyclooxygenase (COX), leading to increased vasopermeability. Reduction of prostaglandin E₂ also reduces its direct inhibitory effect on leukotriene production and on immunological mast cell degranulation.

prostaglandin E₂ formation by COX inhibition has two further effects that promote urticaria: first, by reducing inhibition of cysteinyl leukotriene production and second, by reducing an inhibitory effect on immunologically mediated mast cell degranulation (Fig. 42.5). Cross-sensitivity occurs with other nonselective NSAIDs in susceptible individuals, depending on their pharmacological potency for COX inhibition but not their chemical structure. Although coxibs, which are relatively selective inhibitors of the COX-2 isoenzyme, do not precipitate symptoms in most NSAID-sensitive patients, skin reactions have been reported.

Aspirin and NSAIDs may trigger acute urticaria as well as causing flare-ups of pre-existing chronic ordinary (but not physical) urticaria. Aspirin-induced exacerbations have been reported in 20–40% of patients with CU.^{3,17} Moreover, acute aspirin-induced urticaria appears to be a risk factor for the development of CU.¹⁷ In some patients aspirin may act as a cofactor in food- or exercise-induced anaphylaxis.

Urticaria may develop from a few minutes to 24 hours after following aspirin ingestion but usually starts within 1–2 hours. Angioedema of the lips and tongue, impaired swallowing, and laryngeal oedema develop occasionally. Aspirin-induced skin symptoms usually subside 24–48 hours after its discontinuation. However, severe exacerbations of CU caused by aspirin and other NSAIDs may last from several days to several weeks after aspirin intake.¹⁷

There are no skin tests or reliable *in vitro* diagnostic techniques for patients with aspirin-induced urticaria, and the diagnosis can only be established by challenge tests. Patients should avoid aspirin and other NSAIDs, but coxibs are usually well tolerated and can probably be used safely. Leukotriene receptor antagonists and 5-lipoxygenase inhibitors can be beneficial in the management of aspirin- and NSAID-evoked urticaria, but their efficacy still needs to be confirmed in well-designed studies.¹⁸

Food-induced pseudoallergic reactions in chronic urticaria

Pseudoallergic food reactions appear to be important in some CU patients. Pseudoallergic food triggers include natural salicylates and artificial food additives, such as benzoates and tartrazine. Low-molecular-weight

aromatic compounds in tomatoes, white wine, and herbs have also been implicated.¹⁶ Clinically, exacerbations of CU due to dietary pseudoallergens gradually subside within 10–14 days on an exclusion diet; in contrast, in 1–3 days in allergic urticaria. One study showed increased gastroduodenal and intestinal permeability in CU patients. Those who responded to elimination of pseudoallergens in their diet demonstrated normalization of mucosal permeability and skin symptoms. Although the precise underlying mechanisms for pseudoallergic reactions in CU remain unproven, an impaired gastroduodenal barrier function is likely to be a contributory factor.¹⁹

KININ-MEDIATED ANGIOEDEMA

Angioedema due to C1 esterase inhibitor (C1inh) deficiency and ACEI-induced angioedema involves kinins rather than histamine or leukotriene release. There is currently no evidence that kinins are involved in other types of urticaria or angioedema.

CLINICAL CLASSIFICATION

History-taking and examination define distinctive patterns of urticaria that can indicate the likely pathogenesis, best management, and prognosis for each patient. Six clinical patterns of disease can be recognized.^{3,9} These patterns are not completely distinct and may overlap in some patients.

ORDINARY URTICARIA

Ordinary urticaria is the commonest presentation. The term ‘ordinary’ makes no assumption about etiology, which may include autoimmunity, allergy, pseudoallergy, or infection. Those cases for which a cause cannot be ascertained with reasonable confidence are called idiopathic. In practice, this may be the majority of patients. Ordinary urticaria may be further classified by duration and frequency of attacks into acute, chronic, and episodic urticaria.

Acute urticaria

Acute urticaria is defined as continuous disease lasting less than 6 weeks. People with an atopic predisposition are at higher risk of acute urticaria; atopic diseases are found in about half of acute urticaria patients.³ Most acute urticaria resolves spontaneously within 3 weeks but in 10% patients may progress to CU.

Foods, drugs, and infections are the commonest identifiable causes of acute urticaria, although many cases remain unexplained. Viral upper respiratory tract infections precede the onset of acute urticaria by a few days in 40% of patients.³ Acute urticaria can also be seen in pre-icteric viral hepatitis A, B, and C. However, a specific cause of acute urticaria will not be found in about 50% of patients. Foods are the commonest cause of acute urticaria in children but are rarely responsible for acute urticaria in adults. In infancy, cow's milk allergy is a frequent cause of acute allergic urticaria. Drug-induced urticaria is the commonest presentation of drug hypersensitivity, accounting for a quarter of all adverse drug reactions, with penicillin and NSAIDs the commonest causes of allergic and nonallergic drug-induced urticaria, respectively. Drug-induced urticaria is more likely in the elderly, perhaps reflecting polypharmacy and age-related pharmacokinetic changes, and in patients with human immunodeficiency virus (HIV) infection, renal or liver diseases. Acute NSAID-induced urticaria may be a risk factor for CU.¹⁷

Chronic urticaria

Some 25–50% of patients evaluated in specialist centers with continuous ordinary CU have evidence of functional autoantibodies but the majority remain idiopathic despite investigation.

Episodic urticaria

The cause of episodic urticaria often remains unknown but the possibility of an allergic or pseudoallergic cause needs to be considered.

PHYSICAL URTICARIA

Physically induced urticarias are common, accounting for 25% of all cases of CU. These include dermatographism, cold contact urticaria, delayed-pressure urticaria (DPU), vibratory angioedema, localized heat urticaria, cholinergic, adrenergic, and aquagenic urticarias. Physical urticarias can coexist with chronic ordinary urticaria, and more than one physical urticaria may occur in the same patient (e.g., dermatographic and cholinergic urticarias), which may lead to difficulty in diagnosis. With the exception of DPU, physical urticarias develop rapidly after exposure to the relevant trigger and fade within an hour.^{2,3}

The pathogenesis of physical urticarias is unclear. Physical stimuli lead to nonimmune activation of mast cells resulting in clinical manifestations that relate to the intensity, area, and duration of exposure. A diagnosis of physical urticaria is confirmed if the symptoms can be reproduced by challenge testing with the suspected stimulus. Challenge tests may also be used for monitoring threshold changes during treatment. In general, treatment of physical urticarias includes avoidance of known physical triggers and taking antihistamines. Sometimes tolerance may be induced for cold and solar urticarias.

Fig. 42.6 Extensive induced dermatographic whealing on the chest of a patient due to scratching.

MECHANICAL URTICARIA

Dermatographism

Dermatographism is the commonest physical urticaria, mainly affecting young people. Typical red, itchy, linear wheals are evoked within minutes of stroking, friction, rubbing, or scratching of skin (Fig. 42.6). Overheating, stress, and anxiety usually aggravate symptoms. Transient dermatographism may occur after some bacterial and fungal infections, in scabies, parasitosis, and after treatment with penicillin. The diagnosis of dermatographism is confirmed by stroking the skin with a blunt firm object, usually on the upper back. Antihistamines are the mainstay of therapy. Ultraviolet B radiation may be effective for patients unresponsive to antihistamines.

Delayed pressure urticaria (DPU)

Isolated DPU occurs in just 2% of all urticaria patients but DPU coexists with CU in up to 40% of patients. DPU is the most debilitating of the physical urticarias, and is triggered by sustained local pressure, e.g., wearing tight shoes, carrying heavy bags, long walks, sitting or leaning against firm objects, climbing ladders, jogging, driving, or hand clapping. Deep and painful swellings, clinically resembling angioedema, occur 30 minutes–12 hours after sustained pressure, and may be associated with flu-like symptoms, fever, arthralgia, and fatigue. The most frequent affected sites are hands, soles, buttocks, and shoulders, under straps and belts. DPU lesions last 12–48 hours and are usually painful rather than itchy, especially on the hands and feet. Laboratory investigation reveals transitory leukocytosis and elevated erythrocyte sedimentation rate (ESR). Hanging a heavy weight suspended on a narrow band over the forearm or thigh for 15 minutes may be used as a challenge test but more reliable results can be obtained with a dermatographometer applied at 100 g/mm² for 70 seconds. The reaction should be assessed after 6 hours. DPU is difficult to treat because it responds poorly to antihistamines. High doses of steroids may be required for control in severe cases.

Vibratory angioedema

Vibratory angioedema is very rare. Familial cases have been described. Local swelling develops several minutes to 6 hours after exposure to vibrating machinery, lawn mowing, after applauding and jogging, for instance. Systemic symptoms may occur (headache, tightness in chest, diffuse flare). Placing the hand on a laboratory vortex for 5–15 minutes is a useful challenge test. Avoidance of the trigger is the only helpful treatment strategy.

THERMAL

Cold urticaria

Cold urticaria accounts for about 3% of physical urticarias.²⁰ It occurs in both children and adults, and is commoner in cold climates, in women, and in atopic patients. The majority of cases are primary with no identifiable cause but some cases are secondary to internal disease. Clinical manifestations can be local or generalized. Mucosal involvement may develop after drinking cold beverages. Systemic symptoms can be respiratory (laryngeal angioedema, tongue or pharyngeal swelling, wheezing), vascular (hypotension, tachycardia), gastrointestinal (hyperacidity, nausea, diarrhea), or neurological (disorientation, headache). Cold-induced urticaria can be evoked by low ambient temperature, contact with cold objects, food or beverages, and immersion in cold water. Wheals develop during the cold exposure or, more commonly, on warming up. The severity of cold urticaria depends on the intensity and duration of the cold stimulus. Cold urticaria is potentially life-threatening with a risk of anaphylaxis and death on exposure of large areas to cold, for example jumping into cold water, hypothermia in neurosurgical and cardiothoracic operations. Familial cold urticaria is due to mutations in the cold-induced autoinflammatory syndrome 1 (*CIAS1*) gene and is described below.

In 1–5% of patients, cold urticaria is secondary to cryoproteins (cryoglobulins, cryoagglutinins, cryofibrinogen, cryohaemolysin). These can be associated with infections (hepatitis C, infectious mononucleosis, syphilis, *Mycoplasma* infection), autoimmune diseases, and lymphoproliferative malignancy (Waldenström's macroglobulinemia, myeloma). Cold urticaria may precede these diseases by several years. Secondary cold urticaria can also be drug-related (penicillin, oral contraceptives, angiotensin-converting enzyme (ACE) inhibitors).

The diagnosis of cold urticaria is confirmed by an ice cube challenge, although some atypical cold-induced urticarias have a negative ice cube test.

The clinical workup in cold urticaria includes measurement of cryoproteins. Patients should be cautious about bathing or swimming in cold water, and consuming cold food or drinks. Antihistamine treatment is often helpful but does not prevent anaphylaxis caused by swimming in cold water. In severe cold urticaria tolerance induction may be attempted: this involves depletion of mast cell histamine by repeated cold exposure.

Localized heat urticaria

Heat-induced urticaria is very rare. It is induced by local heating of the skin at 38–50°C. A refractory period up to 24 hours is typical. Challenge test is done by application of hot water in a tube or beaker at up to 44°C for 4–5 minutes. Symptoms develop several minutes after exposure. Management of heat-induced urticaria presents some difficulties as the clinical efficacy of antihistamines is limited.

OTHER PATTERNS

Cholinergic urticaria

Cholinergic urticaria is the second commonest physical urticaria and occurs mainly in adolescents, young adults, and atopic patients. Cholinergic urticaria usually follows a rise in core temperature due to physical exercise, fever, or external passive heat (hot bath, shower, sauna), but may also be provoked by emotional stress and spicy food. The characteristic lesions are highly pruritic pinpoint pale wheals of 1–3 mm surrounded by a red flare. They may occur anywhere except the soles and palms. Lesions usually begin on the trunk and neck, extending outwards to the face and limbs. As lesions progress, confluent areas of whealing and redness may develop. Severely affected patients may develop angioedema and even anaphylaxis. Most patients with mild disease do not seek medical help. The rash is triggered by activation of cholinergic sympathetic innervation of sweat glands but the mechanism of this remains unclear. Decreased blood protease inhibitor levels have been reported, and this is the rationale for using anabolic steroids to treat occasional severely affected individuals who are unresponsive to other measures. The prognosis is reasonably favorable, with spontaneous resolution within 8 years in most patients. However, 30% of patients are affected for >10 years.

Cholinergic urticaria can be confirmed by reproducing the rash with physical exercise or passive heating in a hot bath at up to 42°C. Treatment is primarily with antihistamines, but β -blockers, danazol, ketotifen, and montelukast have also been used. The condition is typically refractory for 24 hours and this may enable patients to prevent attacks by taking daily exercise.

Adrenergic urticaria

Adrenergic urticaria is very rare. The typical lesions are red papular wheals surrounded by a white areola, the opposite of cholinergic urticaria. It is thought that whealing is triggered by local release of norepinephrine. It is provoked by stress and may respond to β -blockers.

Solar urticaria

Solar urticaria affects >1% of all urticaria patients with slight female predominance. It can be associated with erythropoietic porphyria. Wheals are caused by electromagnetic wavelengths ranging from 290 and 760 nm (ultraviolet B, A, and visible spectrum). It develops within minutes or hours after sun exposure and fades within 24 hours. Lesions are usually confined to sun-exposed skin, although they may also develop under clothing. Severity of solar urticaria depends on the wavelength, intensity, and duration of irradiation. Short exposures induce flare and pruritus while longer exposures cause whealing. In patients sensitive to the visible spectrum, reactions may occur through window glass.

Solar urticaria is diagnosed by monochromator phototesting. Patients are advised to use creams with a high sun protection factor (SPF), protective clothing, and protective window shields and limit time spent outdoors. Treatment of solar urticaria includes antihistamines, photochemotherapy and, occasionally, cyclosporine, or intravenous immunoglobulins.

Aquagenic urticaria and pruritus

Aquagenic urticaria is very rare. It occurs in women more often than men and is triggered by water contact but not after drinking water. Scattered small papular wheals, similar to cholinergic urticaria but with a larger flare, appear within 10–20 minutes of water contact and resolve in 30–60 minutes. Diagnosis is made by a challenge test with a wet compress at body temperature for 20–30 minutes on whichever part of the body is usually affected. Associations with HIV infection and hepatitis B have been described.

Aquagenic pruritus without skin lesions is associated with polycythemia, but most cases are idiopathic. Treatment is usually unsatisfactory; phototherapy and sodium bicarbonate in the bathwater have been used.

CONTACT URTICARIA

Contact urticaria occurs locally after skin or mucosal contact with the eliciting agent.^{2,3} Reactions usually develop within a few minutes and resolve over 2 hours, although delayed-contact urticaria can occur with a latent period up to 48 hours. Contact urticaria may be caused by many organic and inorganic stimuli such as latex, animal danders and secretions, foods, plants, topical drugs, and cosmetics.

Allergic contact urticaria occurs mainly in atopic subjects. Sensitization may occur through skin, mucous membranes, respiratory, or gastrointestinal tracts. Foods are the most common cause. In around 15% of patients, contact with the allergen may induce anaphylaxis. The severity of contact reactions depends on many factors (area of exposure, duration of contact, amount and concentration of substance, patient reactivity, comorbidity, and concomitant treatment).

Nonallergic contact urticaria is commoner than allergic contact urticaria and is usually caused by low-molecular-weight chemicals. Contact urticaria to benzoic acid in food is thought to involve generation of eicosanoids because it can be blocked by NSAIDs, but for other substances (e.g., polyvinylchloride, polyethylene glycol) the exact mechanism remains unknown. Nonallergic contact urticaria may occur on first exposure and may depend on dose and concentration of the chemical.

URTICARIAL VASCULITIS

UV is characterized clinically by CU and histologically by leukocytoclastic vasculitis on lesional skin biopsy.^{2-3,21} It is important to differentiate UV from chronic ordinary urticaria in terms of prognosis, approach to diagnostic evaluation, and therapy.

UV affects around 5–10% patients with CU presenting to specialist clinics but is quite rare in the community. It often has a distinct clinical pattern with painful rather than itching wheals lasting over 24 hours leaving residual hyperpigmentation, but may be indistinguishable morphologically from ordinary urticaria. In UV, skin lesions can be accompanied by systemic symptoms, including arthralgia or arthritis affecting mostly the small joints. Other systemic features include abdominal pain, diarrhea, nausea and vomiting, microscopic hematuria and proteinuria, and occasionally episcleritis, uveitis, or conjunctivitis.

The most common laboratory findings in UV are elevated ESR and hypocomplementemia. Circulating immune complexes, low-titer antinuclear antibodies, proteinuria, and hematuria may be present.

Normocomplementemic UV is often idiopathic, limited to skin, and has a better prognosis than hypocomplementemic UV, in which systemic involvement is common. A combination of UV, hypocomplementemia, anti-C1q antibodies, and low serum C1q associated with SLE is termed the hypocomplementemic UV syndrome (HUVS).

Skin biopsy may reveal vascular injury with or without fibrinoid deposits in or around the vessel wall, endothelial swelling, perivascular neutrophilic infiltrate, leukocytoclasia (fragmentation of neutrophils with nuclear dust), and extravasation of red blood cells. Immunofluorescence reveals IgM, IgG immunoglobulins, C3, and fibrin deposition in and around the vessel wall.

Treatment of UV depends on severity of cutaneous involvement and the presence and pattern of systemic symptoms. Prednisolone is widely used but long-term therapy is not recommended because of side effects. Other therapeutic modalities include colchicine and dapsone. Hydroxychloroquine seems to be more efficient in HUVS. For severe UV, azathioprine, mycophenolate mofetil, and cyclosporine can be tried but evidence for these agents is mainly anecdotal.

ANGIOEDEMA WITHOUT WHEELS

Angioedema occurs in nearly half of CU patients, in whom the disease tends to be more severe and more difficult to treat. Angioedema without wheals occurs less frequently but needs specific investigation because it may be due to C1 inhibitor deficiency or drugs, although many cases remain unexplained (Fig. 42.7).

Angioedema due to C1 inhibitor deficiency

The diagnosis, clinical presentation, and management of hereditary and acquired C1inh deficiency are covered in Chapter 20.

Angioedema with normal C1 inhibitor

Angioedema develops in 0.1–2% of patients on ACE inhibitors. It is thought to be due to inhibition of kininase II that breaks down bradykinin as well as converting angiotensin I to angiotensin II in the rennin-aldosterone pathway. It usually presents with episodic and unpredictable swellings of the head and neck, especially of the tongue and oropharynx. Although in most cases angioedema develops within the first week of treatment with ACE inhibitors, the onset of symptoms may occur several years later. Treatment involves discontinuation of ACE inhibitor therapy. Angioedema often recurs on re-exposure to ACE inhibitors. ACE inhibitors can also precipitate angioedema in patients with angioedema due to other causes, including C1inh deficiency. Rare instances of angioedema have also been reported with angiotensin II receptor antagonists.

Angioedema without wheals occasionally occurs with NSAIDs, usually within several hours of intake.

Idiopathic angioedema is diagnosed when no cause can be established. It is generally self-limiting but may follow a prolonged course. Treatment of idiopathic angioedema is as for ordinary urticaria. Antihistamines are the mainstay of therapy; corticosteroids (prednisolone 30–40 mg) are useful for up to 3 days to cover more severe episodes and epinephrine is life-saving in laryngeal angioedema. Tranexamic acid can help in idiopathic angioedema without wheals but it is usually ineffective when angioedema occurs with urticarial wheals.

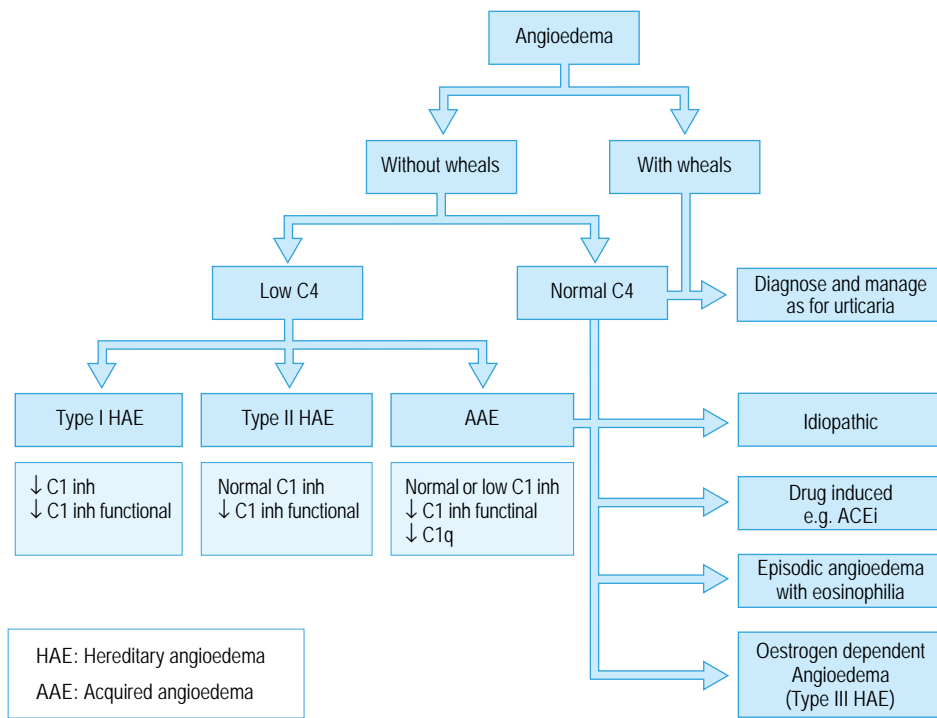

Fig. 42.7 Diagnostic pathway for the differential diagnosis of angioedema.

AUTOINFLAMMATORY SYNDROMES PRESENTING WITH URTICARIA

Acquired Schnitzler's syndrome

Schnitzler's syndrome is a rare form of CU with intermittent fever, bone pain, high ESR, and monoclonal IgM or IgG gammopathy.²² Clinically, patients present with nonpruritic or mildly pruritic CU, mainly affecting trunk and limbs. The wheals are resistant to antihistamines and angioedema is rare. Fever bouts may exceed 40°C, sometimes with chills and nocturnal sweating. Patients often suffer from bone pains, mainly in pelvis or tibiae, arthralgia, and sometimes full-blown arthritis. Lymphadenopathy, hepato-, and splenomegaly may be present.

Kappa light-chain monoclonal IgM and, less commonly, IgG paraproteins are found on serum electrophoresis. The ESR is persistently elevated at 60–100 mm/h, with leukocytosis, elevated platelet count, and anemia. Skin histology shows neutrophilic urticaria in most cases; monoclonal IgM is deposited in the epidermis around the keratinocytes and along basement membranes on direct immunofluorescence. Bone examination demonstrates hyperostosis on radiography and hyperfixation on bone technetium scanning. Bone marrow examination is normal in most patients, but shows nonspecific lymphocytic, plasmacytic, or polyclonal infiltration in about 20%.

The pathophysiology of Schnitzler's syndrome is still unclear and the severity of CU does not depend on the paraprotein level. Evidence of activation of IL-1, increased IL-6, and granulocyte-macrophage

colony-stimulating factor and anecdotal reports of complete clinical responses to the IL-1 receptor antagonist, anakinra, suggest a leading role for cytokines in its pathogenesis.

The prognosis is generally benign. However, long-term follow-up is recommended because patients may develop B-cell lymphomas 10–20 years after its onset.

First-line treatment of Schnitzler's syndrome is with NSAIDs, and colchicine or dapsone. In severe cases with disabling fever or arthralgia, oral corticosteroids and immunosuppressive drugs (cyclosporine, cyclophosphamide, and interferon-α) have been used, but treatment of the paraprotein is not effective.

HEREDITARY (CRYOPYRIN-ASSOCIATED) PERIODIC SYNDROMES

Several hereditary autoinflammatory urticarial syndromes show mutations of the *CIAS1* gene on chromosome 1q44. *CIAS1* encodes a protein called cryopyrin, which is involved in apoptosis and inflammation. These rare autosomal dominant disorders include familial cold autoinflammatory syndrome (FCAS), Muckle-Wells syndrome (MWS), and chronic infantile neurological cutaneous and articular syndrome (CINCA).²³

Familial cold autoinflammatory syndrome

Periodic fever and urticaria are induced by generalized cold exposure.²⁰ Disease onset is usually at birth or within the first 6 months of life. Papular or plaque-like wheals develop in response to chilling but not

local contact with cold water or an ice cube. Skin lesions occur after a few hours, subside in 24 hours, and are usually accompanied by fever, chills, conjunctival injection, sweating, headache, and arthralgia. During attacks there is marked leukocytosis, elevated ESR, and raised C-reactive protein.

Muckle–Wells syndrome

MWS develops in children or adolescents. It is characterized by CU, fever, aching, and malaise. Sensorineural deafness may develop in adulthood. Some MWS patients develop systemic amyloidosis (AA-type) with amyloid nephropathy. Laboratory findings in MWS include elevated ESR, C-reactive protein, IL-6, IL-1, and serum amyloid-associated protein.

Chronic infantile neurological cutaneous and articular syndrome

CINCA syndrome is more severe than FCAS or MWS, with neurological features and arthritis. Urticaria is rarely observed in infancy; other clinical features are lymphadenopathy, hepatosplenomegaly, dysmorphic features, developmental retardation, seizures, papilloedema, neurological manifestations, and overgrowth of the distal femur and patella. Affected individuals are at risk of leukemia and other malignancies, infections, and systemic amyloidosis.

Recently, it has been shown that treatment with the IL-1 receptor antagonist, anakinra, leads to complete resolution of symptoms in FCAS and MWS with normalization of inflammatory indices.

DIFFERENTIAL DIAGNOSIS

Several dermatoses may present with urticarial lesions, including erythema multiforme minor, bullous pemphigoid, and dermatitis herpetiformis.^{2,3} These dermatoses can nearly always be distinguished clinically from urticaria on the basis of their polymorphic pattern, prolonged duration of individual lesions, lack of daily fluctuation, development of vesicles or blisters, and resistance to conventional therapy for urticaria. Very occasionally, skin biopsy, with or without indirect immunofluorescence, may be required to make the distinction.

Papular urticaria is an urticarial reaction to insect bites in sensitized individuals. The lesions are fixed rather than fluctuating, may take days or weeks to resolve fully, and may leave pigmentation or scars. Bites often occur asymmetrically in groups or lines. Although histamine is involved with the initial pruritic lesions, oral antihistamines are usually unhelpful and potent topical steroids may be required.

WORKUP IN URTICARIA PATIENTS

Evaluation of patients with urticaria requires a detailed history and physical examination.^{1-4,24} The history is particularly important in urticaria patients and should include a thorough search for all potential causes of the disorders, possible precipitating and aggravating factors, the timing of onset and duration of individual wheals, associated symptoms as well as travel history, recent infection, occupational exposure, food and

CLINICAL PEARLS

DIAGNOSIS OF CLINICAL PATTERNS OF URTICARIA

- >> The duration of individual wheals can help to define the pattern of urticaria
- >> Wheals lasting an hour or less are usually triggered by a physical stimulus
- >> Localized wheals lasting up to 2 hours may be due to skin or mucosal contact with an allergen or a nonimmunological exposure
- >> Wheals that take 1–24 hours to fade are usually a presentation of the ordinary pattern of chronic urticaria
- >> Wheals lasting more than 24 hours may be due to delayed-pressure urticaria or urticarial vasculitis

drug intake, and comorbidity. Patients can be asked to keep a diary of attacks, which may provide additional information about possible causes. The duration of individual lesions can be very helpful in distinguishing the different clinical patterns of urticaria.

Physical examination should focus on skin lesion morphology and careful systemic evaluation. If the patient is symptom-free at the time of evaluation, photographs may be helpful. The approximate duration of individual lesions can be assessed by outlining a particular lesion with a pen and observing it for a day. The appearance and distribution of skin lesions may suggest a diagnosis—for example, the pinpoint lesions with a large flare in cholinergic urticaria or lesions on sun-exposed areas in solar urticaria. A thorough physical examination can also offer diagnostic clues for associated comorbidities, including thyroid dysfunction.

Further evaluation of patients with urticaria is guided by the patient's history and clinical pattern of disease. However, it must be remembered that there may be more than one cause for urticaria and that different clinical subtypes of urticaria may coexist in one patient.

WORKUP IN ACUTE URTICARIA

It is well established that allergies are common causes of acute urticaria. The culprit allergens can be suspected from the clinical history, including a close temporal relationship to the time of exposure to the allergen and a history of previous exposure and prompt resolution on allergy withdrawal. Therefore, patients with acute or episodic urticaria should undergo allergy evaluation by skin testing or radioallergen sorbent test (RAST) investigation if clinically indicated. In the case of food allergy, positive test results must also be verified by a trial of elimination diet followed by double-blind food challenge in supervised clinical settings.

WORKUP IN PHYSICAL URTICARIAS

When physical urticaria is suspected, appropriate challenge testing should be performed to confirm the diagnosis. Generally, there is no need for further investigations, except for cold urticaria where plasma cryoproteins (cryoglobulin, cold agglutinin, or cryofibrinogen) should be assayed.

WORKUP IN CHRONIC ORDINARY URTICARIA

No laboratory workup is recommended for patients with mild ordinary CU that is easily controlled by antihistamines, unless the history points to an underlying disease. Studies have shown that random laboratory testing very rarely yields evidence of unsuspected internal diseases as a cause of CU and this should therefore be discouraged.²⁵

Screening laboratory evaluation can be considered in patients with poor response to first-line treatment. A complete blood count with differential, ESR, thyroid-stimulating hormone, liver function tests, and urinalysis will exclude most diseases associated with urticaria.

Other evaluations should be guided by abnormal findings in the history and physical examination in patients with CU. Additional tests may include stool examination for ova and parasites, antinuclear antibody titer, thyroid function and antithyroid antibodies, hepatitis viral screen, skinprick tests, or RAST for IgE-mediated reactions in episodic urticaria. Tests for immediate hypersensitivities should not be undertaken in chronic continuous urticaria unless there are compelling reasons for doing so. Rarely, CU can be caused by a specific food additive, which should be confirmed by dietary exclusion and double-blind, placebo-controlled oral challenge.

THE DIAGNOSIS OF AUTOIMMUNE CU

The diagnosis of autoimmune CU is not straightforward and involves *in vivo* and *in vitro* approaches. Autologous serum skin testing (ASST) is a simple and useful screening method for functional autoantibodies in CU patients. For skin testing, 0.05 ml of the patient's own serum should be injected intradermally into clinically uninvolved forearm skin together with an equal volume of saline and histamine (10 mg/ml) as controls at adjacent sites. The reaction is considered positive if the serum skin test forms a pink wheal at least 1.5 mm greater than the negative control at 30 minutes. The test is 80% specific and 70% sensitive for autoimmune CU as defined by a positive basophil histamine release assay.¹³ A strongly positive ASST response (over 15 mm) was reported to be very specific for autoimmune CU (> 96%) when a panel of basophil and mast cell donors was used for testing.²⁶

The current diagnostic gold standard in autoimmune CU is functional release assays using basophils or mast cells, but these only give indirect evidence of functional autoantibodies. Being technically difficult and time-consuming, these assays remain confined to research centers. Moreover, immunoassays (Western blotting, ELISA) based on binding of autoantibodies to relevant antigens (FcεRIα or IgE) do not correlate well with the results of functional assays.¹⁴

MANAGEMENT OF URTICARIA

Finding effective treatment for urticaria can be challenging for both clinician and patients. Treatment should be tailored to the clinical pattern, duration, and severity of the urticaria. Management should include nonpharmacological measures and drug therapy with a stepwise approach.^{9,26,27}

GENERAL MEASURES

Identification and avoidance of allergens, infections, and physical triggers are of primary importance. Patients with the ordinary pattern of CU should minimize exposure to nonspecific aggravating factors, identified by a thorough history that may include overheating, stress, alcohol, dietary

THERAPEUTIC PRINCIPLES

MANAGEMENT OF URTICARIA

- >> Eliminate infectious, drug, or food causes
- >> Minimize nonspecific aggravators, including heat, stress, alcohol, nonsteroidal anti-inflammatories, and pressure
- >> Regular oral antihistamines are the first line of therapy for all patterns of urticaria, except C1 esterase inhibitor deficiency
- >> Second-line treatments, including short courses of oral corticosteroids, may be necessary for specific clinical situations
- >> Immunosuppressive therapies should be reserved for patients with severe autoimmune urticaria or steroid-dependent urticaria that has not responded to other first- and second-line measures

pseudoallergens, and some drugs. NSAIDs aggravate CU in up to 30% of patients with the ordinary presentation and should generally be avoided. This probably does not apply to the physical urticarias, in particular DPU, where NSAIDs may be used as treatment. ACE inhibitors are contraindicated in angioedema without wheals and should be prescribed with caution in other patterns of urticaria. Although it is often recommended that CU patients should avoid codeine and penicillin, clinical experience suggests that this is not necessary. Cooling lotions and creams such as 1% menthol in aqueous cream may help to relieve pruritus. Some patients with ordinary but not physical CU appeared to respond to a low-pseudoallergen diet.¹⁶ However, controlled clinical trials are lacking.

FIRST-LINE THERAPY

Antihistamines are the cornerstone of treatment in urticaria. Second-generation antihistamines offer several advantages over classical H₁ antihistamines, such as lack of sedation and impairment of performance, longer duration of action, and absence of anti-cholinergic side effects. Meta-analysis indicates that antihistamines are clinically effective in 40–90% of patients with CU. Second-generation antihistamines are inverse agonists of H₁ receptors, which stabilize H₁ receptors in the inactive conformation, and, therefore, are most effective in CU when taken regularly for prophylaxis. The timing of antihistamine intake should be adjusted to suit the diurnal pattern of urticaria. It has become common practice to increase second-generation antihistamines above their licensed doses when CU does not respond, because clinical experience shows that this achieves better control in some patients, although hard scientific evidence is still lacking. Although the evidence base for combining H₁ and H₂ antihistamines is poor, this may be helpful in some patients. Cimetidine (but not ranitidine) appears to increase the plasma concentration of H₁ antihistamines by inhibiting hepatic cytochrome P450. H₂ antihistamines also suppress the dyspepsia that often accompanies severe urticaria.

SECOND-LINE THERAPY

When urticaria does not respond to first-line measures, systemic corticosteroids are commonly used as short-term therapy for acute urticaria or severe exacerbations of CU. Long-term treatment with

corticosteroids is not recommended because of safety concerns. In corticosteroid-dependent patients, an alternate-day dosing may be used and steroid-sparing drugs should also be considered. A wide variety of medications have been reported to be of benefit for antihistamine-unresponsive urticaria when oral corticosteroids might otherwise have to be considered but they are invariably used off-license and controlled trials are usually lacking. Where possible, these should be targeted at specific subgroups of urticaria patients, e.g., the leukotriene receptor antagonist montelukast has been shown to be effective in aspirin-sensitive CU patients, and thyroxine in biochemically euthyroid CU patients with evidence of thyroid autoimmunity.²⁸

THIRD-LINE THERAPY

Immunosuppressive therapy is mainly considered for autoimmune CU.^{3,13} However, clinical experience suggests it may also benefit therapy-resistant CU without evidence of circulating antibodies.

The best-studied immunosuppressive therapy is cyclosporine, which has been shown in a double-blind placebo-controlled study to be effective at 4 mg/kg daily in CU patients. Patients must be monitored carefully for renal function and hypertension; treatment should normally be limited to 3 months. Cyclosporine is contraindicated for patients with previous malignant disease. Tacrolimus also appears to be effective in corticosteroid-dependent autoimmune CU.¹⁸ There is some evidence for efficacy of plasmapheresis and immunoglobulins in chronic autoimmune urticaria, though these are expensive options and controlled clinical trials are needed. Methotrexate and azathioprine have also been used alone or with corticosteroids.

ANAPHYLAXIS

Anaphylaxis is a severe, life-threatening, systemic reaction involving difficulty with breathing, circulatory collapse or both.

Epidemiology of anaphylaxis

Estimates of the incidence of anaphylaxis in the general population vary from 3.2 cases per 100 000 inhabitants per annum in Denmark to 21 cases per 100 000 inhabitants per annum in the USA.²⁹ The mortality rate is estimated to be in the range of 1–2%.³⁰ In the UK anaphylaxis accounts for 20 deaths per year, which represents 1 death in 3 million people.³¹ Anaphylaxis occurs more often in females than males³² and in children more than adults.³³

Hospital admissions for anaphylaxis nearly doubled in the UK in the 1990s.³⁴ Severe anaphylaxis was diagnosed in 1–9 per 10 000 people attending emergency departments in the UK, Australia, and the USA.³⁰ It is estimated that, in a 12-month period, 1 in 12 patients with previous anaphylaxis will have a recurrence, and 1 in 50 will require hospitalization or treatment with epinephrine.³³

The pathophysiology of anaphylaxis

Although anaphylaxis is often subdivided into allergic (IgE-mediated) and nonallergic (anaphylactoid) groups, the clinical presentation is similar and some authorities do not make a distinction. In IgE-mediated anaphylaxis, allergen cross-links allergen-specific IgE antibodies on the surface of mast cells and basophils, leading to their degranulation in the

same way as in allergic urticaria. Release of mediators causes bronchoconstriction, mucus secretion, diminished cardiac contractility, increased vascular permeability, vasoconstriction of coronary and peripheral arteries, and vasodilation of venules, thereby producing clinical symptoms of anaphylaxis. IgE-mediated reactions occur in presensitized patients (e.g., penicillin-, insulin-, latex- or peanut-induced anaphylaxis). By contrast, some substances such as opioids, radiocontrast media, and some muscle relaxants are capable of direct mediator release (histamine) from basophils and mast cells without involvement of IgE. Although reactions to NSAIDs are considered to be pharmacological rather than immunological due to the downstream effects of COX inhibition, an IgE-mediated mechanism has been suspected in a few patients but is difficult to prove. Apart from IgE, other antibodies may be involved: in murine models IgG-mediated FcεRIII-dependent anaphylaxis elicited by a high dose of allergen has been described. The key participating cells in this type of anaphylaxis are macrophages, with platelet-activating factor as the main mediator.³⁵

The etiology of anaphylaxis

A cause of anaphylaxis can only be identified in about 60% of patients. Anaphylaxis is most commonly caused by foods, drugs, general anesthetic agents, insect stings, and latex. Rare causes include vaccines, semen, and aeroallergen inhalation. Exercise may occasionally cause anaphylaxis either on its own (exercise-induced anaphylaxis), or after prior ingestion of a food to which the individual is sensitized (food and exercise-induced anaphylaxis). Idiopathic anaphylaxis accounts for up to 40% of all cases.^{35,36} Patients with idiopathic anaphylaxis should be investigated to exclude systemic mastocytosis.

The most common routes of allergen exposure are oral and parenteral, although inhalation of allergens (for example, fish or legume allergens after cooking, latex particles in health care settings) or percutaneous penetration after skin contact can induce anaphylaxis in highly sensitized patients. The link with atopy is not clear but anaphylaxis with predominant respiratory involvement elicited by skin and mucosal allergen contact is thought to be more often related to atopy than parenterally induced anaphylaxis (e.g., insect stings or drug-induced anaphylaxis).³⁵

Food-induced anaphylaxis

Food allergy is a common cause of anaphylaxis, with an annual incidence of 7.6 cases per 100 000 person-years.³⁵ Anaphylactic reactions to foods have been increasing over the last two decades: a fivefold increase in food allergy was reported in France from 1980 to 1995.³⁰ Food-induced anaphylaxis is the most common single cause of anaphylaxis treated in emergency departments in the USA, especially in the younger population, and accounts for 29 000 estimated emergency room visits and 150–200 deaths per year.³⁵ Over 60% of cases of food-induced anaphylaxis occur in patients younger than 30 years.³⁷ Peanuts and other nuts, fish, and shellfish are the most frequent culprits in food-induced anaphylaxis but almost any food can be implicated.³⁷ Many cases of severe anaphylaxis are caused by unintended exposure to hidden food allergens. In addition, alcohol, NSAIDs, exercise, or concurrent infection may increase the severity of a food-induced allergic reaction.

Drug-induced anaphylaxis

Drug-induced anaphylaxis is more common in hospitalized patients than in the community. Any drug may cause anaphylaxis, though the prevalence varies: one study found 5–15 cases per 100 000 patients for most NSAIDs and antibiotics, while for penicillin and contrast agents the figure was over 30 cases per 100 000.³⁸ Drugs are the leading cause of fatal anaphylaxis, comprising 43.5% of such deaths.³¹ The mortality rate in drug-induced anaphylaxis is about one death per 50 000–100 000 treatment courses.³⁸ All routes of administration can be potentially fatal, including oral, intravenous, intra-articular, intrauterine, inhalational, rectal, or topical, but the risk is greatest after parenteral administration.

Anaphylaxis during anesthesia

The incidence of anaphylaxis in general anesthesia varies between 1:3500 and 1:20 000, significantly exceeding the overall prevalence of drug-induced anaphylaxis.³⁶ The French registry of anaphylaxis during general anesthesia established a prevalence of one case in 13 000 episodes of general anesthesia.³⁹ The incidence of anaphylaxis to local anesthetics is, by contrast, extremely rare. Most cases of suspected anaphylaxis to local anesthetics are probably due to vasovagal or panic attacks; a few may follow inadvertent intravascular injection.

A network of 38 French allergeo-anesthesia outpatient clinics reported that around 60% of all cases were induced by muscle relaxants (rocuronium, suxamethonium, etc.), followed by latex and antibiotics.³⁹ Reactions to neuromuscular blocking agents mostly occur on first exposure and were associated with a 70% rate of cross-reactivity in this group. Latex, the next most important cause of anaphylaxis, accounted for 16% of intraoperative anaphylactic reactions.³⁹

Insect sting-induced anaphylaxis

Severe anaphylaxis from insect stings causes approximately 40 deaths annually in the USA and nearly 100 in Europe.²⁷ The intensity of reaction depends on the type of insect, amount of venom, location of sting, and the patient's sensitivity. Allergen-specific immunotherapy with venom extracts has been shown to be safe and effective in patients with hymenoptera venom allergy, providing some clinical protection within the first 8 weeks of treatment and a long-lasting effect after 3–5 years of maintenance treatment (Chapter 43). It is noteworthy that patients with systemic mastocytosis are at risk of potentially fatal anaphylaxis to insect stings even if they are not presensitized to venom: this may be due to venom components, such as phospholipase A₂, acting as mast cell liberators. Venom immunotherapy may be given to mastocytosis patients but there is quite a high risk of anaphylaxis during treatment.

Latex-induced anaphylaxis

The prevalence of latex allergy has been estimated to be as high as 1–6% in the general population, 8–17% in health care workers, and 67% in spina bifida patients.²⁹ Latex-induced anaphylaxis has been reported in surgery and dentistry and can be fatal. More than half of latex-allergic patients have allergies to fruits such as bananas, avocado, kiwi fruit, chestnut, pears, pineapples, grapes, and papayas.

Other rare causes of anaphylaxis

Anaphylaxis occurs during 1 in 20 000–47 000 transfusions of blood or blood products, especially in patients with IgA deficiency.⁴⁰ IgA deficiency affects 1 in 500–700 Caucasians. One-third of these patients have circulating anti-IgA antibodies, which are associated with serious life-threatening anaphylactic reactions to blood products containing IgA.

Seminal fluid allergy is extremely rare, mostly affecting atopic young women, with 20% of cases developing life-threatening anaphylaxis. These reactions can be prevented with condom usage or intravaginal desensitization with seminal fluid.

Idiopathic anaphylaxis

Idiopathic anaphylaxis is a diagnosis of exclusion. Its pathophysiology is not understood.

THE CLINICAL DIVERSITY OF ANAPHYLAXIS

In anaphylaxis, there is a remarkable range of clinical symptoms. Anaphylaxis can be preceded by prodromal symptoms such as tingling and redness of the palms and soles, anxiety, sense of doom, and disorientation. Anaphylaxis most commonly begins in the skin and mucous membranes, followed by involvement of the respiratory and gastrointestinal tracts, cardiovascular system and, finally, proceeding to cardiac and/or respiratory arrest. Generalized urticaria and angioedema are the most common manifestations of anaphylaxis observed in over 90% of cases, but may be absent. Respiratory symptoms may vary from rhinitis to laryngeal edema and airway obstruction, which are potentially life-threatening. Some patients present with only cardiovascular collapse in the absence of other signs of anaphylaxis, especially during general anesthesia.⁴¹ The differential diagnosis of anaphylaxis includes panic attacks and vasovagal episodes.

Four clinical patterns of anaphylaxis have been described: immediate, biphasic, protracted, and delayed.³⁵ Anaphylaxis can occur within seconds after allergen exposure: the more rapid the onset of anaphylaxis after allergen exposure, the more severe and life-threatening the reaction. Food-induced anaphylaxis takes slightly longer to develop than drug- or insect-induced anaphylaxis. Up to 20% of patients may have biphasic anaphylaxis, with recurrence 2–12 hours after the initial attack. Recurrent episodes do not differ clinically but may require more epinephrine. The occurrence of biphasic anaphylaxis cannot be predicted from the severity of the initial attack. Some patients may develop protracted anaphylaxis, which sometimes lasts longer than 24 hours, may be extremely severe, and is often resistant to treatment. Delayed onset of anaphylaxis has been reported anecdotally but is very unusual in clinical practice.

The diversity and severity of symptoms in anaphylaxis depend on the route of allergen exposure, the extent of allergen absorption, the degree of sensitization, individual allergen threshold, target tissue sensitivity, cofactor involvement, comorbidity, and concomitant treatment. Recently, "summation anaphylaxis" has been recognized if it occurs after simultaneous exposure to various stimuli (physical exercise, infection, stress or concomitant exposure to other allergens or treatment with NSAIDs, ACE inhibitors, or β -blockers).³⁵ Fatal reactions to foods are usually characterized by respiratory symptoms (bronchospasm and hypoxia). In contrast, anaphylaxis induced by insect stings is more likely to lead to cardiovascular collapse. Asthma sufferers are at higher risk of fatal anaphylaxis. The risk of relapse

CLINICAL PEARLS

DIAGNOSIS OF ANAPHYLAXIS

- >> Anaphylaxis is characterized by extreme difficulty with breathing due to airway obstruction from angioedema or bronchoconstriction, circulatory collapse or both
- >> It is nearly always accompanied by tachycardia, usually by flushing, urticaria, and panic, and sometimes by vomiting and diarrhea
- >> Panic attacks do not involve airways obstruction, hypotension, or urticaria but may be accompanied by faintness or tetany of the hands due to rapid overbreathing
- >> Vasovagal attacks present with fainting, nausea, slow pulse, and pallor without respiratory difficulty, diarrhea, or urticaria

in anaphylaxis depends on the type of allergen, individual allergen threshold, success of allergen avoidance, and the availability of immunotherapy.

The most dangerous symptoms are laryngeal edema, respiratory failure, and circulatory collapse, which may lead to death. Deaths from acute asthma in anaphylaxis occur predominantly in patients with pre-existing unstable asthma. Rapidly fatal shock often occurs without other symptoms, while death from laryngeal angioedema is the least common cause of fatality. According to the UK fatal anaphylaxis registry, the earliest arrest in fatal food anaphylaxis develops within 25–35 minutes of exposure, slightly slower than for insect stings (10–15 minutes) or drugs (5 minutes or less in hospital and 10–20 minutes outside hospital).^{31,35}

THE DIAGNOSIS OF ANAPHYLAXIS

The measurement of blood tryptase level is now widely used as a marker of mast cell degranulation for *in vitro* confirmation of anaphylaxis. Beta-tryptase is released from mast cells but not from basophils and diffuses more slowly than histamine. The concentration of tryptase peaks 1–2 hours after the onset of reaction and remains elevated with a half-life of 1.5–2.5 hours. The samples for tryptase testing should be collected within 6 hours of anaphylaxis onset and again after 24 hours to check that the value has returned to normal. Tryptase can also be detected in postmortem specimens after death from suspected anaphylaxis.³¹

Normally, mature tryptase is below detection limits in the serum of healthy subjects, while it is elevated in most cases of anaphylaxis with vascular compromise, especially if it is parenterally induced. A tryptase concentration above 25 µg/l is highly suggestive of anaphylaxis.³⁹ However, a normal level of tryptase is quite often observed in food-induced anaphylaxis so a normal tryptase result does not exclude anaphylaxis.^{35–37} The diagnostic value of other mast cell proteases in anaphylaxis is under investigation.

THE MANAGEMENT OF ANAPHYLAXIS

Early recognition of anaphylaxis facilitates removal of the cause and prompt institution of treatment. The patient with anaphylaxis should lie down with the legs elevated in order to increase venous blood return and maintain cardiac output. In drug-induced or insect-induced anaphylaxis a tourniquet may be placed proximal to the site of the injection or insect sting to slow

absorption of injected antigens. The tourniquet should be released for 3 minutes at 5-minute intervals, with the total duration of application not exceeding 30 minutes. Epinephrine should be administered at the first sign of respiratory failure or cardiovascular collapse. Milder attacks of allergy are often treated with antihistamines as a first-line measure. Epinephrine auto-injectors for self-administration are available but a single pen may be insufficient to reverse severe reactions. Their use in anaphylaxis outside hospital can be life-saving. The earlier epinephrine is administered in anaphylaxis, the better the outcome and survival rate.⁴² Overall, prompt diagnosis of anaphylaxis, early administration of epinephrine, and fast transport to emergency rooms are crucial factors for successful management of anaphylaxis.

Epinephrine is both an α - and β -adrenergic agonist with cyclic adenosine monophosphate (cAMP)-mediated pharmacological effects on target organs. In patients with anaphylaxis, stimulation of α_1 -adrenergic receptors increases peripheral vascular resistance, thereby improving blood pressure and coronary perfusion, reversing peripheral vasodilation, and decreasing angioedema. Activation of β_1 -adrenergic receptors increases myocardial contractility (inotropy, chronotropy) while stimulation of β_2 -adrenoreceptors causes bronchodilation as well as decreasing the release of inflammatory mediators from mast cells and basophils.^{35,42}

According to current recommendations, the intramuscular route for epinephrine administration is preferable to the subcutaneous route due to faster absorption and higher plasma level of epinephrine after intramuscular injection.⁴⁰ The appropriate dosage of epinephrine is 0.3–0.5 ml of a 1:1000 dilution for adults. Epinephrine has a rapid but short action, therefore the dose can be repeated every 5–15 minutes until symptoms improve. More than one dose is required in one in three patients. The intravenous administration of epinephrine (1:10 000 dilution, i.e., 100 µg/ml) should be reserved for severe anaphylaxis with profound life-threatening hypotension that is refractory to other treatment because of a risk of potentially fatal cardiac arrhythmias and myocardial infarction.

Common pharmacological adverse effects of epinephrine include anxiety, fear, headache, pallor, tremor, dizziness, and palpitation. In the event of overdose, unwanted effects may include increased QTc interval on electrocardiography, ventricular arrhythmias, angina, myocardial infarction, increased blood pressure, pulmonary edema, and intracranial hemorrhage. Patients with cardiovascular diseases and thyrotoxicosis and cocaine users are particularly prone to adverse effects of epinephrine.

The efficacy of epinephrine can be decreased by concomitant therapy with β -blockers, which is associated with unopposed stimulation of α -adrenoreceptors and reflex vagotonic effects, leading to bradycardia, hypertension, coronary artery constriction, bronchoconstriction, and augmented mediator release. Anaphylaxis in patients on β -blockers can be severe, protracted, and unresponsive to treatment. Patients treated with β -blockers may require fluid replacement and treatment with glucagon, which increases intracellular cAMP independently of β -adrenergic receptors. Glucagon can be administered in an intravenous bolus of 1 mg, followed by infusion of 1–5 mg/hour. Glucagon may improve hypotension in 1–5 minutes with maximal effect at 5–15 minutes. Side effects of glucagon include nausea and vomiting.

Corticosteroids are often administered in anaphylaxis to minimize the risk of recurrent or protracted anaphylaxis. The beneficial effects of corticosteroids develop 6–12 hours after administration. Therefore, their main role in anaphylaxis is likely to be the prevention of relapse but it is still unclear how they work.

If no response to epinephrine is observed, life support measures should be instituted. The treatment choice depends on the clinical presentation. In resistant hypotension, large volumes of fluids (crystalloids) should be

given rapidly to compensate for peripheral vasodilatation and for fluid loss into the extravascular space. Other vasopressors (dopamine, glucagon) may be needed to reverse severe hypotension. Oxygen should also be administered in circulatory or respiratory failure. Bronchospasm should be treated with nebulized or inhaled β_2 -agonists. If there is severe laryngeal edema, endotracheal intubation and even emergency tracheostomy may be needed to maintain the airway. All patients should be observed in a hospital setting for at least 4 hours because of the risk of biphasic anaphylaxis. In severe cases, an observation period of 24 hours is advisable.

THE PREVENTION OF ANAPHYLAXIS

The first step in prevention is to identify those at risk of anaphylaxis. Therefore, all patients with a history of anaphylaxis should be referred for assessment and undergo allergy evaluation. Patients should be instructed how to avoid culprit allergens and cross-reactive agents and should be advised on safe alternatives. The education of patients, their families and, in the case of children, caregivers and school staff about anaphylaxis and first-aid measures is of primary importance. Written treatment plans should be provided to patients at special risk. Emergency medications such as epinephrine auto-injectors should be dispensed and patients should receive training on their usage. Patients should be advised to carry an epinephrine auto-injector with them at all times. Immunotherapy is very effective for prophylaxis of bee and wasp venom-induced anaphylaxis in sensitized patients and can be life-saving. Prevention strategies for anaphylaxis should also involve public awareness and public health measures, such as appropriate food labeling, disclosure of food ingredients in restaurants, the withdrawal of peanuts from in-flight refreshments, first-aid training in anaphylaxis for school staff, and establishing national anaphylaxis registries.

Allergic reactions to stinging and biting insects

Ulrich R. Müller, Gabrielle Haeberli, Arthur Helbling

43

INTRODUCTION

Insects can induce allergic reactions by stinging and biting. They sting humans to defend themselves; they bite to nourish. With regard to allergies, stings by insects of the order Hymenoptera (bees, wasps or ants) are much more important than bites, which can be inflicted by various insects such as mosquitoes, horseflies, midges, fleas and bed bugs. Stings by Hymenoptera can induce acute systemic allergic reactions that kill several hundred patients in Europe and America every year, whereas systemic allergic reactions to bites are very rare. Both stings and bites can induce local allergic or toxic reactions. Infections are only transmitted by bites.

ENTOMOLOGICAL ASPECTS^{1,2}

Stinging Hymenoptera all belong to the suborder Aculeatae (Fig. 43.1) with the families Apidae, Vespidae, Formicidae and Myrmicidae.

APIDAE

In this family the honeybee (*Apis mellifera*) (Fig. 43.2A) is clinically the most important cause of allergies. Stings occur either in the vicinity of beehives or when the insect feels threatened during human activities, such as cutting flowers or walking barefoot in the grass. Because the whole beehive survives over the winter, stings can occur not only in spring and summer, but occasionally also on warm winter days. Honeybees are brown and moderately hairy. In contrast to other Hymenoptera, when stinging they usually lose their barbed sting.

Bumblebees (e.g., *Bombus terrestris*) are increasingly used as pollinators in greenhouses and occasionally cause allergic sting reactions in greenhouse workers.² Bumblebees are definitely larger than honeybees, more hairy, and most species have distinct yellow or white bands on their abdomen (Fig. 43.2B).

VESPIDAE

The vespids are divided into the subfamilies Vespinae and Polistinae, which differ morphologically in the junction between thorax and abdomen (Fig. 43.2C, D). Vespids are almost hairless, and in most species the abdomen is striped black and yellow. Vespids do not usually lose their sting when stinging and may therefore sting several times, even the same victim. Because only the queen survives over winter, larger populations develop only in summer and most stings occur in summer and fall. The subfamily Vespinae contains the three genera *Vespula*, *Dolichovespula* and *Vespa*.

Vespula (*V. germanica* and *V. vulgaris* in Europe, *V. maculifrons* and *V. germanica* in USA) are called wasps in Europe and yellowjackets in the USA. They breed in the ground, in attics or in shelters. The genus *Vespula* is by far the most aggressive. Stings occur not only near the nests, but more often while victims are eating outdoors.

Most species of *Dolichovespula* (*D. media*, *D. sylvestris*, *D. saxonica* in Europe, *D. maculata*, *D. arenaria* in USA) look very similar to *Vespula*, with black and yellow stripes on the abdomen and only a slightly larger size. They can be distinguished from *Vespula* by the larger distance between the eyes and the mandibles. Only *D. maculata*, the bald-faced hornet in the USA, is easy to distinguish from other vespids by its mostly black abdomen. *Dolichovespula* build their nests in tree branches or under the roofs of houses. They sting almost exclusively in the vicinity of their nests.

The genus *Vespa* (*V. crabro*, the European hornet, *V. orientalis*) is easy to distinguish from other vespids by its much larger size. The European hornet has been introduced to America. The oriental hornet is present in southeastern Europe, Asia and Africa. Hornet stings are rare and occur almost exclusively in the vicinity of nests, which are usually in hollow tree trunks or bird nest-boxes.

Polistinae (*P. annularis*, *P. exclamans*, *P. fuscatus* in USA, *P. dominulus*, *P. gallicus* and *P. nympha* in Europe) live mostly in southern USA and in the Mediterranean area of Europe, but small colonies have been observed

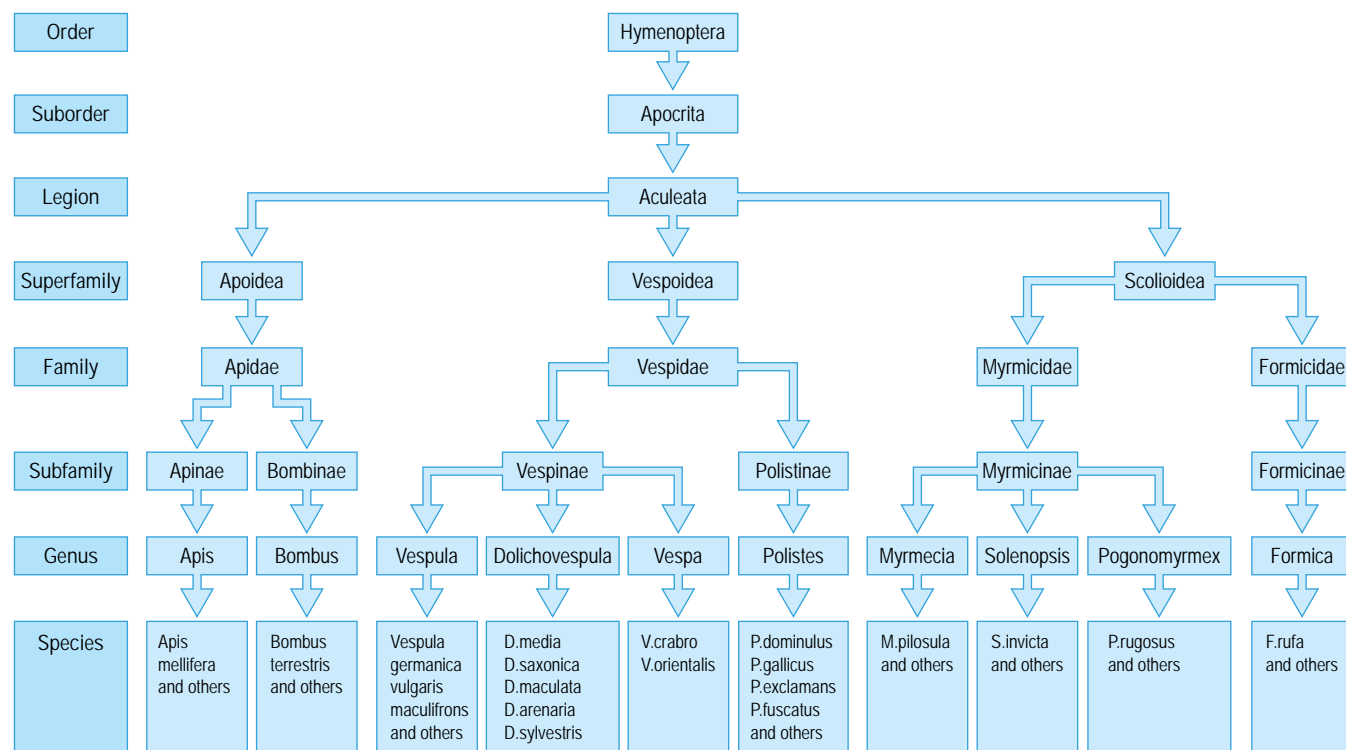

Fig. 43.1 Taxonomy of Hymenoptera.

all over Europe except for the British Isles. Their small nests consist only of one womb and are built in trees or under roofs.

ANTS (MYRMICINAE, FORMICINAE)

In south and central America, and in the southern states of the USA, the fire ants (*Solenopsis invicta*, *S. richteri*) are responsible for many systemic allergic sting reactions.³ Fire ants build their mounds in yards, playgrounds and fields. Occasional allergic sting reactions have been described to *Pogonomyrmex*, the North American harvester ant, and extremely rarely to the European red ant, *Formica rufa*. In contrast, species of Myrmecinae, especially *Myrmecia pilosula*, the jack-jumper ant, are an important cause of allergic sting reactions in southern Australia.⁴

ALLERGENS IN HYMENOPTERA VENOMS

All Hymenoptera venoms contain low molecular weight substances such as biogenic amines, phospholipids, amino acids and carbohydrates, and peptides such as melittin, apamin or kinins, which contribute to the toxic effect but which – except for melittin – are probably irrelevant with regard to allergies. The allergens of the important stinging Hymenoptera are shown in Table 43.1. Most of them are glycoproteins of 10–50 kDa. The major allergens in bee venom are phospholipase A2, hyaluronidase and acid phosphatase; in vespid venoms antigen 5, phospholipase A1 and

hyaluronidase. Ant venom from *Solenopsis invicta* contains a 37 kDa and a 24 kDa allergen with some sequence homology to phospholipase A1 and to antigen 5 from vespid venom. Today the genes of many major venom allergens have been cloned, and some of them have also been expressed as recombinant proteins that are comparable in allergenic activity and enzymatic function to their natural counterparts.^{5–7}

The amount of venom injected during a sting varies between and within species, especially with vespids. Bees release 50–140 µg venom per sting; vespids much less: between 2 and 17 µg.²

CLINICAL PICTURE

Symptoms of venom hypersensitivity are most often due to IgE-mediated, but occasionally to nonIgE-mediated immunologic mechanisms. Rarely nonimmunologic mechanisms of mediator release play a role. The clinical presentation is classified into normal, large local, systemic allergic, systemic toxic and unusual reactions.^{1,2}

NORMAL LOCAL REACTIONS

The normal local reaction of a nonallergic subject to a Hymenoptera sting consists of a painful, sometimes itchy, local wheal and flare reaction, followed by a swelling of up to 5–10 cm in diameter. Usually, local symptoms resolve within a few hours, by definition within 24 hours. After stings by *Solenopsis*, the American fire ant, a vesicle remains which later develops into a pustule that only heals after 1–2 weeks.³

Fig. 43.2 Common Hymenoptera. (A) Honey bee (*Apis mellifera*). (B) Bumblebee (*Bombus terrestris*). (C) Wasp/yellowjacket (*Vespula* spp). (D) Field wasp (*Polistes gallicus*).

LARGE LOCAL REACTION (LLR)

We define an LLR as a swelling around the sting site exceeding 10 cm in diameter, developing minutes to hours after the sting and lasting over 24 hours.¹ LLR may be very disturbing, especially when they last for days or even weeks and involve a whole limb, eyelids or lips. Sometimes they are accompanied by lymphadenopathy or lymphangitis. They may also be associated with nonspecific systemic inflammatory symptoms, such as malaise, fever, shivering, or headache. However, the development of a local infection, an abscess or phlegmon at the sting site is inhibited by the bacteriostatic effect of Hymenoptera

venoms. In contrast, scratching after stings by the American fire ant *Solenopsis* or bites from blood-sucking insects such as midges, can lead to skin infection.

The pathogenesis of LLR is thought to be based on IgE- and cell-mediated immune mechanisms or a combination of both.^{1,2}

SYSTEMIC ALLERGIC REACTIONS (SR)

Systemic anaphylactic reactions are usually mediated by IgE. Affected organs can include the skin (pruritus, urticaria, flush, angioedema), the gastrointestinal tract (cramps, vomiting or diarrhea, dysphagia), the

CLINICAL RELEVANCE

CLASSIFICATION OF SYSTEMIC ALLERGIC HYMENOPTERA STING REACTIONS (ACCORDING TO MUELLER,⁸ WITH MODIFICATIONS¹)

- >> *Grade I* Generalized urticaria, itching, malaise, anxiety
- >> *Grade II* Any of the above plus two or more of the following: angioedema, chest constriction, nausea, vomiting, diarrhea, abdominal pain, dizziness
- >> *Grade III* Any of the above plus two or more of the following: dyspnea, wheezing, stridor, dysarthria, hoarseness, weakness, confusion, feeling of impending disaster
- >> *Grade IV* Any of the above plus two or more of the following: fall in blood pressure, collapse, loss of consciousness, incontinence, cyanosis

respiratory tract (laryngeal edema, bronchial obstruction, pulmonary edema) and the cardiovascular system (arterial hypotension, shock, arrhythmias, loss of consciousness with incontinence).

The most commonly used classification of SR was developed by Mueller⁸. Symptoms appear most often within minutes to 1 hour after the sting. The patient recovers usually within a few hours. Rarely a protracted course over more than a day or a biphasic course has been described.

Lasting morbidity – e.g., myocardial or cerebrovascular infarction – as a consequence of SR, or even fatal reactions can occur, but are rare (see Epidemiology).

SYSTEMIC TOXIC REACTIONS

Toxic reactions are dose dependent and a clinically significant toxic effect must be considered only after multiple – usually 50 to several hundred – stings.^{1,2} The main toxic effects develop within hours to days and comprise rhabdomyolysis and intravascular hemolysis leading to acute renal failure with tubular necrosis. Myocardial damage, hepatic dysfunction, coagulation disorders as well as brain edema and/or necrosis may occur. The number of stings needed to cause a fatal reaction varies between 200 and 1000 in adults. In small children, however, fewer than 50 stings may be lethal. In most cases death occurs only after several days.

UNUSUAL REACTIONS

Unusual sting reactions are rare and appear after hours to days. More than half of them follow immediate local or systemic reactions.^{1,8} Non-IgE-mediated immunologic mechanisms may play a role. The causal relation to the sting event often remains uncertain. Serum sickness-like syndromes with fever, arthralgias, exanthema and lymphadenopathy are well documented. Less frequently reported complications following Hymenoptera stings include diseases of the nervous system (peripheral neuropathy, polyradiculomyelitis, extrapyramidal syndromes, acute disseminated encephalomyelitis), of the kidneys (glomerulonephritis, interstitial nephritis), of blood and blood vessels (hemolytic anemia, thrombocytopenia, Henoch-Schönlein syndrome and other forms of vasculitis).⁹

Fig. 43.3 Deaths after insect stings in Switzerland 1961–2003.

EPIDEMIOLOGICAL ASPECTS

PREVALENCE OF ALLERGY TO STINGS BY FLYING HYMENOPTERA

In subjects 16–65 years of age cumulative lifetime sting rates of 61–95% have been reported.¹⁰ Of course this can vary considerably in different regions of the world. Hymenoptera sting allergy may occur at any age. In general, as a result of their outdoor activities, men are more frequently stung than women, children more often than adults.

The reported cumulative lifetime prevalence of LLR ranges from 2% to 26%, that of SR from 0.3% to 7%.² In beekeepers it varies between 14% and 43%.¹¹

RISK FACTORS FOR HYMENOPTERA ALLERGY

The risk of developing a sting allergy increases with the number of stings. It is especially high if two stings occur within a short period (a few weeks to 2 months).¹² Beekeepers stung less than 10 times a year, however, have a much higher risk for SR than those stung more than 200 times a year.¹¹

Cardiovascular diseases and treatment with β -blocking drugs and ACE inhibitors are associated with more severe sting reactions. However, β -blockers do not increase the overall risk of systemic sting reactions.¹³ Atopy is no more frequent in Hymenoptera sting-allergic patients than in the general population. In an atopic patient with Hymenoptera venom allergy, however, systemic reactions may be more severe and more often affect the respiratory tract. About 50% of venom-allergic beekeepers are atopic. In atopic beekeepers sensitization may also occur by inhalation of dust containing venom during work on the beehives.¹¹

MORTALITY DUE TO HYMENOPTERA STINGS

Mortality from Hymenoptera stings varies from 0.09 to 0.48 deaths per million inhabitants per year.¹⁴ The annual incidence of fatal Hymenoptera sting reactions of about 150 in Europe and 40

in the United States is probably an underestimate. The vast majority of fatal sting reactions occur in adults over 45 years of age.^{2,14} Additional risk factors include a positive history of sting allergy, male gender, and stings on the head or neck.¹² Autopsies have documented pre-existing cardiovascular disease in most cases.¹⁴ Approximately half of the deaths occur in subjects with no known prior history of allergic sting reactions. Annual deaths rates in Switzerland from 1961 to 2003 are depicted in Figure 43.3.

NATURAL HISTORY OF HYMENOPTERA STING ALLERGY (TABLE 43.2)

In prospective clinical studies, the risk of developing a systemic reaction after a LLR is between 5% and 10%; after a mild SR between 15% and 30%; and after a severe SR between 50% and 75%. The degree of severity of an index sting reaction is an important factor determining the risk at re-exposure. Children are at a lower re-sting risk than adults.¹⁵ The re-sting risk is definitely lower in *Vespula*-allergic than in bee-venom-allergic patients, probably because of the smaller and more variable amount of venom injected.

EPIDEMIOLOGIC ASPECTS OF ALLERGIC REACTIONS TO ANT STINGS

Nearly 50% of inhabitants of fire-ant-endemic areas of the USA are stung each year.³ Many report LLR. However, up to 1% of patients who are stung by imported fire ants develop anaphylaxis, and some deaths have been reported. In Australia more than 90% of ant venom anaphylaxis is caused by *Myrmecia pilosula*. Age over 35 years, annual sting rate, and allergy to bee venom were predictors for more severe reactions. Deaths have also been reported.¹⁶

Table 43.2 Natural history of Hymenoptera venom allergy

Previous reaction	Author, year	Re-exposure by*	% with systemic reaction upon re-exposure to			
			Bee or vespid*	Bee	Vespid	Ant
Large local	Müller, 1990	FS	6

	Müller, 1979	FS		75		
	Brown 2003	CH				72

*FS = field sting
CH = sting challenge.

DIAGNOSIS

HISTORY

The clinical history is the basis of the diagnosis of Hymenoptera sting allergy. This includes the date, number and circumstances of stings (e.g., environment, activities); kind and severity of symptom; sting site; retained or removed stinger; interval to onset of symptoms; emergency treatment; risk factors for a particularly severe reaction (e.g., comorbidity, drugs); tolerated stings after the first systemic reaction; and other allergies.^{1,2} In individuals with only an LLR no further diagnostic tests are recommended. Basic diagnostic tests are skin tests and estimation of venom-specific serum IgE antibodies.

SKIN TESTS

Skin tests should be performed at least three weeks after an SR in order to avoid false negative results during the refractory period. They are performed by intradermal or skin-prick endpoint titration;² 0.02 mL of venom solution are injected intradermally in increasing concentrations – from 0.001 to 1 µg/mL – into the volar surface of the forearm. For skin-prick tests, concentrations of 0.01–300 µg/mL are used. However, even at 300 µg the sensitivity of skin prick is clearly lower than that of the intradermal test. We therefore prefer the intradermal test.

VENOM-SPECIFIC SERUM IgE ANTIBODIES (sIgE)

Several different *in vitro* immunoassays for the detection of sIgE have been derived from the original RAST (radio allergosorbent test) and are commercially available. Immediately after a sting sIgE may be low or even undetectable, but usually increases within days or weeks after an SR. If no sIgE is detectable, the test should be repeated after 2–4 weeks.²

SENSITIVITY AND SPECIFICITY OF SKIN TESTS AND sIgE

The sensitivity of these tests is over 90% in patients with a history of SR within the last year. As a rule the intradermal test remains positive longer than sIgE. However, so far no reliable test exists to predict the risk of future SRs in untreated or treated patients. In spite of a history of typical SRs to stings, a few patients have no detectable IgE and negative skin tests.¹⁷ This may be due to insufficient sensitivity of the available tests, a long interval between SR and testing, with spontaneous decrease of sensitization, or nonIgE-mediated pathogenesis.

Specificity may cause problems: about 10–20% of people without a history of SR have a positive diagnostic test. Although sensitization following a previous sting is difficult to exclude, this positivity may reflect cross-reactivity (see below).

CROSS-REACTIVITY

Cross-reactivity between venom allergens is strong within a species, e.g., between *Vespula*, *Dolichovespula* and *Vespa*, but only limited between *Vespinae* and *Polistinae* and honeybees and bumblebees. Between bee and vespid venom there is little cross-reactivity on protein basis, mainly due to an about 50% sequence identity between hyaluronidases of the two families, but double positivity with diagnostic tests to both venoms is frequently observed. This may reflect true double sensitization or cross-reactivity. Besides partial sequence homology of hyaluronidase, carbohydrate-containing epitopes are important. Cross-reacting carbohydrate determinants (CCDs) are present in many major Hymenoptera venom allergens, such as hyaluronidase, acid phosphatase and phospholipase A2, but also in many plant proteins, e.g., in rapeseed pollen or bromelain. CCDs are certainly responsible for part of the double positivity of diagnostic tests to bee and vespid venoms. They may also explain some of

the positive tests in individuals with no history of SR. The CCDs are probably of no clinical relevance.¹⁸ The RAST-inhibition test with venoms and CCDs is helpful in distinguishing between true double sensitization and cross-reactivity, and assisting in the choice of venoms for immunotherapy, but it is not always conclusive.

For ant allergy, only whole-body extracts are commercially available. Their diagnostic sensitivity and specificity are not well documented.

CELLULAR TESTS

If routine tests in patients with a history of SR are negative, cellular tests may be helpful to demonstrate sensitization.²

In the *basophil histamine release test* peripheral blood leukocytes are incubated with venom allergens. The reaction with cell-bound IgE antibodies leads to histamine release from basophils. In the *cellular antigen stimulation test* (CAST) leukocytes of patients are pre-stimulated with IL-3 and exposed to venom allergens. The released sulfidoleukotrienes are determined by ELISA.

The *basophil activation test* is based on flow-cytometric demonstration of an altered membrane phenotype of basophils stimulated by IL-3 and allergen exposure. At present the most commonly used expression marker is CD63.

Cellular tests are expensive and not yet well standardized; data on sensitivity, specificity and predictive value are still scarce.

ALLERGEN-SPECIFIC IgG (sIgG)

The presence of specific IgG and IgG₄ primarily reflects exposure to the respective venom. sIgG titers increase after a sting, irrespective of the presence or absence of an allergic sting reaction. Venom immunotherapy induces a rise in sIgG. However, there is no close correlation between the concentration of sIgG or the sIgE/sIgG ratio and the clinical response to immunotherapy.¹ Routine assessment of sIgG is therefore not recommended.

BASELINE SERUM TRYPTASE

Because of the association of an elevated baseline serum tryptase level (>11.4 µg/l) with especially severe, sometimes IgE-negative, systemic sting reactions and cutaneous or systemic mastocytosis, this enzyme should be determined in all patients with a history of SR.¹⁹ The commercially available fluorescence immunoassay measures total tryptase. α-Tryptase is secreted continuously and reflects whole-body mast-cell load. Elevated values are seen in cutaneous and systemic mastocytosis. β-Tryptase is released during mast cell activation, and is a marker of anaphylaxis.

STING CHALLENGE TESTS

Sting challenge with a live insect is not recommended as a diagnostic tool in untreated patients. A sting challenge under well supervised clinical conditions may, however, be helpful in evaluating the efficacy of venom immunotherapy.²⁰ A tolerated sting challenge does not, however, definitely exclude a reaction to future stings after immunotherapy, especially if these are repeated.

PREVENTION AND TREATMENT

PREVENTION

All patients with a history of SR should receive detailed instruction on the avoidance of future stings and measures to take if re-stung. Bee stings occur most often when walking barefoot on grass, wasp stings when eating outdoors, in orchards with fallen fruits and near open waste-bins. The risk of a sting is especially high near beehives or vespid nests. While gardening, long trousers, shirts with long sleeves and gloves are recommended. Strongly scented perfumes, suncreams or shampoos, as well as brightly colored garments, should be avoided.

TREATMENT OF LARGE LOCAL REACTIONS

Oral antihistamines and cooling of the sting site (e.g., with ice cubes) reduces local swelling, pain and itching. Anti-inflammatory ointments or topical corticosteroids may diminish the local inflammatory process. In cases of severe swellings oral corticosteroids together with antihistamines over several days are recommended.²¹

SYSTEMIC ALLERGIC REACTIONS

Sympathomimetics, antihistamines and corticosteroids are the most effective drugs for symptomatic treatment of SR. All patients with SR should be medically observed until the symptoms resolve and the blood pressure is stable.

Mild reactions confined to the skin may be treated with rapidly acting oral antihistamines alone. If respiratory or cardiovascular symptoms occur, intramuscular epinephrine must be given immediately, intravenous access should be established, and antihistamines and corticosteroids given IV. All patients with severe SR should be hospitalized and supervised until completely recovered. Patients with cardiovascular symptoms must be treated and transported in the supine position, and IV volume replacement is indicated.

Every patient with a systemic allergic sting reaction should be investigated by an allergist with a view to prevention measures and immunotherapy.²¹

EMERGENCY MEDICATION KIT

All patients with a history of SR should carry an emergency kit for self-administration. After a sting patients should immediately take both antihistamines and corticosteroids, whether there are symptoms or not. If systemic symptoms such as urticaria, dyspnoea, generalized weakness or dizziness occur, epinephrine should be administered IM in the lateral thigh via an auto-injector Epipen (0.3 mg of epinephrine). In children below 30 kg bodyweight the Epipen junior (0.15 mg epinephrine) and half the dose of antihistamines and corticosteroids should be used. If any SR occurs, medical care must be sought.

VENOM IMMUNOTHERAPY (VIT)²¹

Indications

VIT is indicated in children and adults with a history of severe systemic reactions (grade III/IV), if sensitization to the relevant venom is demonstrated by skin and/or blood test. LLR or unusual

THERAPEUTIC PRINCIPLES

EMERGENCY TREATMENT OF GENERALIZED ALLERGIC REACTIONS TO HYMENOPTERA STINGS

Symptoms	Medication	Other measures/comments
Mild urticaria, angioedema	Antihistamines Oral or parenteral	Check: blood pressure, peak flow or FEV ₁ Observation for 1–2 hours
Severe urticaria, angioedema	Antihistamines Parenteral or oral Corticosteroids 0.5–1.0 mg/kg bodyweight Epinephrine Adults: 0.3–0.5 mg IM Children: 0.01 mg/kg IM	Check: blood pressure, peak flow or FEV ₁ Observation until symptoms disappear completely
Laryngeal edema	Epinephrine inhaled IM	Oxygen supply In more severe cases intubation and tracheotomy may be necessary
Bronchial obstruction	β ₂ -agonists or epinephrine	Oxygen supply
Anaphylactic shock	Epinephrine (if necessary repeated after 10 minutes) Adults: 0.3–0.5 mg IM Children: 0.01 mg/kg IM Volume replacement Antihistamines and corticosteroids IV Dopamine or norepinephrine continuous infusion Glucagon: 0.1 mg/kg IV	Place in supine position, oxygen supply Hospitalization for 24 hours advisable (risk of biphasic reaction) In case of protracted hypotension or shock inpatients on β-blockers

reactions do not qualify for VIT. In patients with repeated mild, non-lifethreatening reactions who are at high risk for re-exposure, such as beekeepers or their family members, VIT is also recommended. Concomitant cardiovascular disease, mastocytosis or strongly impaired quality of life due to the venom allergy are also indications for VIT in patients with non-lifethreatening sting reactions.²²

Contraindications for VIT are the same as for immunotherapy with other allergens. Treatment with β-blockers or ACE inhibitors is a relative contraindication: these drugs should preferably be replaced. In all patients with coronary heart disease, arrhythmias or cardiac failure, where the protective effect of these drugs is well documented, the situation should be evaluated carefully together with the family practitioner and a cardiologist.¹³

Dosage and treatment regimens

The recommended maintenance dose is 100 µg of the venom, for both children and adults. This maintenance dose is equivalent to approximately two bee stings or several vespid stings. A higher dose (e.g., 200 µg) is recommended when systemic reactions occur after re-exposure to a field sting or a sting challenge. In highly exposed subjects such as beekeepers or professional gardeners a maintenance dose of 200 µg is advised.

VIT may be initiated by a conventional or an ultra-rush protocol (Table 43.3). The injection interval for maintenance VIT is 4 weeks for the first year. Afterwards intervals may be extended to 6 weeks if VIT is well tolerated.

THERAPEUTIC PRINCIPLES

EMERGENCY MEDICATION FOR SELF-ADMINISTRATION

Prescribed emergency drugs	Epinephrine auto-injector (e.g. Epipen) Antihistamine tablets with rapid action (e.g. cetirizine 2 × 10 mg) Fexofenadine 2 × 180 mg) Corticosteroid tablets (e.g. prednisolone 2 × 50 mg)
Procedure if stung	Take the four emergency tablets as above immediately Prepare Epipen for injection If any systemic allergic symptoms arise, apply Epipen immediately in the lateral thigh; seek medical care

Adverse reactions to VIT

The overall incidence of systemic adverse reactions to VIT varies between 5% and 40%. VIT with bee venom causes more side effects than with *Vesputula* venom. Ultra-rush protocols are associated with a somewhat higher rate of side effects than conventional protocols. Most systemic side effects are mild; approximately one-third will require medical treatment.

Fig. 43.4 Biting insects that may cause allergic reactions.

Premedication with antihistamines reduces large local and other cutaneous reactions such as urticaria, but severe systemic reactions may not be suppressed. Many authors recommend giving antihistamines 2 hours before injections in the up-dosing phase of VIT until the maintenance dose has been repeatedly well tolerated.

Efficacy of VIT

In addition to three prospective controlled trials, the efficacy of VIT has been confirmed by well-tolerated sting challenges during VIT in a number of uncontrolled prospective studies.²⁰ Treatment with bee venom results in full protection in 80–85% of patients; with *Vespula* venoms in 95–100%. The efficacy of immunotherapy with commercially available *Solenopsis* whole-body extract has not been documented in controlled studies. However, excellent results, comparable to those of VIT with *Vespula* venom, were obtained in a double-blind placebo-controlled study using *Myrmecia pilosula* venom.⁴

Duration of VIT

Lifelong treatment may be the safest recommendation, but after some years of VIT the majority of allergic individuals may lose motivation. Studies that addressed the protection rate 1–7 years after discontinuation of VIT of at least 3 years' duration showed persisting protection in over 80% of both adults and children. In most allergy centers VIT is recommended for at least 5 years. Even longer treatment should be considered in high-risk patients such as those with very severe systemic sting reactions, coexisting cardiovascular or pulmonary disease, systemic allergic reactions to VIT or stings during VIT, and for subjects with elevated basal serum tryptase levels. Lifelong VIT is advised for patients with cutaneous or systemic mastocytosis. Three of the four reported cases of fatal sting reactions after stopping VIT were in patients with mastocytosis.²¹

Risk factors for recurrence of systemic reactions after stopping VIT

A number of risk factors have been identified for relapse of Hymenoptera venom allergy after discontinuation of VIT: generally adults have a less favorable prognosis than children. Bee-venom-allergic patients have a higher relapse risk than those allergic to *Vespula* venom. The more severe the pre-treatment reactions were, the higher the risk for recurrence of systemic reactions following Hymenoptera stings. After VIT for 5 years, compared to only 3 years, the risk of relapse is reduced.

Table 43.3 Protocols for venom immunotherapy

Week	Conventional		Ultra-rush	
	Amount of venom (µg)	Day	Minutes	Amount of venom (µg)
1	0,01	1	0	0,1
2	0,1		30	1

10	60			
11	80	21	0	100
12	100	49	0	100

ALLERGIC REACTIONS TO BITING INSECTS

Biting insects may cause local allergic reactions as a result of sensitization to their salivary proteins introduced during the process of blood sucking. Systemic reactions are very rare. The responsible insects belong to the orders Diptera, Hemiptera and Siphonaptera²³ (Fig. 43.4).

CLINICAL SYMPTOMS

Local reactions to insect bites may comprise immediate wheal and flare, or be delayed, with pruritic erythema and papules developing after 12–24 hours and lasting for days to weeks; combined reactions can also occur. In delayed and combined reactions, vesicular, bullous or even necrotic lesions may develop. Systemic reactions are much rarer than to Hymenoptera stings. They have, however, occasionally been described, especially following bites by horseflies (*Tabanus* spp.) and the kissing bug (*Triatoma protracta*).

ALLERGENS

The salivary proteins involved have either digestive (amylases, esterases) or hemostatic function (e.g., factor Xa inhibition). Numerous IgE-binding proteins with a molecular weight of 15–81 kDa have been described, especially in the saliva of mosquitoes, but also in horseflies and kissing bugs; some of these have been cloned.²⁴

PREVENTION AND TREATMENT

The application of insect repellents and prophylactic intake of antihistamines can prevent or mitigate outdoor exposure.²⁵ Screens on windows and doors and mosquito nets over the beds are effective in homes. Bedbug infestation should be eliminated by appropriate pesticides; flea infestation of pet animals should be managed by a veterinarian.

Local reactions may be treated with topical steroids or oral antihistamines.

Immunotherapy for allergic reactions is controversial, because only whole-body extracts are commercially available for diagnosis and treatment.

FUTURE PERSPECTIVES

The availability of recombinant venom allergens offers several promising perspectives for both diagnosis and immunotherapy.^{5,6} The specificity of these tests could be considerably improved by using recombinant cocktails with all major allergens for diagnosis instead of the whole venom. In patients with double-positive diagnostic tests using honeybee and *Vespula* venom, recombinant species-specific nonglycosylated major allergens from honeybee and *Vespula* venom should make it possible to distinguish reliably between true double sensitization and cross-reactivity, an important issue for the choice of venoms for immunotherapy.

The efficacy and safety of VIT with vespid venoms are excellent, but in bee-venom-allergic patients VIT is associated with significantly more side effects and is also less effective. With cocktails of point-mutated recombinant allergens, or of T-cell epitope peptides of bee venom allergens, it should be possible to reduce the side effects of immunotherapy with bee venom and increase the maintenance dose, and hence the efficacy of treatment.²⁶

Atopic and contact dermatitis

Thomas Bieber

44

Atopic dermatitis (AD) is a chronic and relapsing inflammatory skin disease affecting an increasing number of patients.^{1,2} Characteristic features of AD include pruritus and chronic or chronically relapsing dermatitis, usually beginning during infancy. AD is a genetically complex disease and is often, but not always, accompanied by other atopic disorders such as allergic rhinoconjunctivitis or allergic bronchial asthma. These diseases may appear simultaneously or develop in succession during the course of disease. AD characteristically starts during early childhood, whereas allergic rhinitis and asthma predominate in adolescence. This characteristic, age-dependent sequence has been termed the *atopic march*.³ The cutaneous manifestations of atopy often represent the beginning of this atopic career while asthma is its full expression. Therapeutic strategies should be directed towards the delay or avoidance of this development, by early intervention against skin inflammation which may prevent subsequent sensitization and progression towards rhinitis and asthma.

AD is a genetically complex disease involving gene–gene and gene–environment interactions, but much progress in understanding its pathogenesis has been achieved in recent years. Genetic linkage studies have identified several chromosomal regions linked to epidermal barrier function, and genetic variants which favor the development of AD, but several candidate genes linked to the immune system have also been detected. Stress, bacterial or viral infections, exposure to aero- or food allergens and hygienic factors have been implicated in aggravating the symptoms of AD. Although the so-called ‘hygiene hypothesis’ is controversial, the importance of lifestyle and environment in the mechanisms of atopic disease is well accepted. Additionally, a generalized Th2-deviated immune response is closely linked to AD, but the skin disease itself is a biphasic inflammation with an initial Th2 phase, while chronic lesions harbor Th0/Th1 cells. Both regulatory T cells (Tregs) and the innate immune system have been shown to be altered in AD. The main treatment goals for AD include the elimination of inflammation and infection, preservation and restitution of barrier function, anti-pruritic management, and control of exacerbating factors. In the longer term, the strategy in AD will likely aim to control skin inflammation in order to prevent the emergence of sensitization.

KEY CONCEPTS

PATHOPHYSIOLOGY OF ATOPIC DERMATITIS

- >> Atopic dermatitis is a genetic complex disease (gene–gene and gene–environment interactions)
- >> Defective epidermal barrier function and decreased epidermal innate immunity
- >> Deviated immune response toward increased sensitization supported by skin inflammation
- >> High microbial colonization which amplifies skin inflammation
- >> Role of FcεRI/IgE-bearing dendritic cells
- >> Role of IgE-mediated immune response to autoallergens
- >> Decreased activity of regulatory T cells

DEFINITION

Over the last 120 years, AD has been given a multitude of different names, e.g., *Besnier's prurigo*, *disseminated neurodermitis*, or *neurodermitis constitutionalis sive atopica*, but *atopic dermatitis* and *nonatopic dermatitis* are currently the most widely used names. According to a recent consensus nomenclature by the World Allergy Organization (WAO), the term AD should be reserved for the eczematous condition with the typical clinical signs and associated with immunoglobulin E (IgE)-mediated sensitization to aeroallergens. Indeed, in 2004 a WAO consensus group proposed a revised terminology for atopy, restricting its use to conditions associated with IgE sensitization.⁴ According to this classification, the term atopy should only be applied in combination with documented allergen-specific IgE antibodies in serum or with a positive skin prick test. This current terminology substitutes the former term of *extrinsic AD* and includes only patients who show IgE sensitization against inhalant and/or food allergens in skin tests or serum. A small group of approximately 20–30% of affected patients show clinical signs of AD, without

any IgE-sensitization. This group may be classified as having ‘nonatopic dermatitis,’ replacing the previous term *intrinsic AD*. Patients with *nonatopic dermatitis* show negative skin tests and have no other signs of IgE-mediated sensitization. Both *atopic* and *nonatopic dermatitis* are most probably highly related, in terms of natural history of the disease, as will be discussed below.

From an etymological perspective, dermatitis means any dermal inflammation, while eczema (from greek Εκζεiv=boiling) is more an epidermal acute inflammation with vesicles. Nevertheless, in order to be consistent and not to complicate the issue in this chapter, the term ‘dermatitis’ will be used, although both ‘eczema’ and ‘dermatitis’ are used interchangeably by physicians worldwide.

EPIDEMIOLOGY

With an incidence of 15–30% in children and 2–10% in adults, AD has clearly increased by two- to threefold during the past three decades in industrialized countries.⁵ AD usually presents during early infancy and childhood but may also persist into adulthood or start in adulthood. In 45% of affected children the onset of AD occurs during the first 6 months of life; during the first year 60% of the children are affected, and 85% of those who will be affected will show symptoms before the age of 5. The severity of AD seems to be linked to sensitization to foods, in particular hen’s egg and cow’s milk. Interestingly, however, more than 50% of children in the first 2 years of life do not display any sign of allergic sensitization even though they suffer from classical skin lesions.⁶ The prevalence of AD in rural areas is significantly lower, emphasizing the importance of lifestyle and environment in the mechanisms of atopic disease. This is in line with previous studies underlining the influence of microbial exposure in early life on the subsequent development of atopic disorders – the ‘hygiene hypothesis,’⁷ a concept that is currently hotly debated.⁸

CLINICAL MANIFESTATIONS

It should be emphasized that nonatopic dermatitis and AD are not clinically different; both develop on dry skin that may in some instances resemble a mild form of ichthyosis. Intense pruritus is also a common feature of both forms of dermatitis. The clinical spectrum is wide, ranging from mild forms such as pityriasis alba, to major forms with erythrodermic variants. The dermatitis is polymorphic, with acute (oozing, crusted, vesicles, or papules on erythematous plaques), subacute (mainly excoriated plaques), and chronic (lichenified and excoriated plaques) forms. Although pruritus can occur throughout the day, it generally worsens at night and can profoundly affect the quality of life.

Clinical patterns usually vary with age. The first signs of inflammation typically occur during the third month of life and infants present with facial and patchy or generalized dermatitis (Fig. 44.1). Lesions generally first appear on the cheeks and are characterized by dry and erythematous skin with papulovesicular lesions. The term ‘milk crust’ or ‘milk scurf’ refers to the occurrence of yellowish crusts on the scalp that are similar to scalded milk. At a later age, the inner and outer parts of the arms and legs may also be affected. The diaper area is usually spared. Itching and scratching are intense and promote the tendency to bacterial superinfection, mainly by *Staphylococcus aureus*. In childhood, sites of predilection of

Fig. 44.1 Facial lesions in atopic dermatitis.

dermatitis are flexural areas and the dorsum of the feet and hands. They can either develop from the preceding neonatal phase or arise *de novo*. Rashes usually begin with papules that go on to become lichenified. The skin around the lips may be inflamed and constant licking of the area may lead to small, painful cracks in the perioral skin. For unknown reasons, in more than 60% of cases AD may enter into complete remission during puberty.

As in childhood, localized inflammation with lichenification of the flexural areas is the most common pattern of adult AD. Sites of predilection are the neck, upper chest, large joint flexures, and backs of the hands. If the face is affected, this is usually on the forehead, eyelids, and perioral region. Scalp involvement can occur and may even lead to diffuse hair loss. During adulthood, even if the inflammation has resolved, dry skin continues to be a persistent problem, especially in winter months. In adults some minimal variants of AD may occur such as hand dermatitis, nummular dermatitis, periocular inflammation, lichenification of the anogenital area, cheilitis sicca, nipple dermatitis, and pityriasis alba.

COMPLICATIONS

The most important complications of AD are due to secondary infections. It has been shown that deficiency in anti-microbial peptides (AMP; see below) for host defense and possibly a reduced cell-mediated immunity over years contribute to the occurrence of bacterial and viral complications. Nearly all AD patients have their skin heavily colonized by *Staphylococcus aureus*, although clinical signs of infection are mostly lacking. In children with strong pruritus and excoriations, impetigo-like crusting can develop.

Patients with AD are at increased risk for fulminant herpes simplex virus infections (eczema herpeticum).⁹ The course of this complication can be severe, with high fever and widespread eruptions. Clinically, numerous vesicles in the same stage of development are characteristic. Patients feel systemically unwell and the diagnosis should be confirmed rapidly by polymerase chain reaction. It remains unclear whether the prevalence of viral warts or molluscum contagiosum is increased in AD.

HISTOLOGY AND IMMUNOHISTOLOGY

The histology of both forms of dermatitis is similar to that of allergic contact dermatitis (ACD) and has no fundamental impact on the diagnosis of AD. Clinically normal appearing skin of AD patients contains a sparse perivascular T-cell infiltrate suggesting minimal inflammation.¹⁰ Acute papular skin lesions are characterized by marked intercellular edema (spongiosis) of the epidermis (Fig. 44.2). Langerhans cells (LC), in lesional and, to a lesser extent, in nonlesional skin of AD frequently exhibit surface-bound IgE molecules. In acute lesions there is a marked perivascular T-cell infiltrate in the dermis with monocytes-macrophages. The lymphocytic infiltrate consists predominantly of activated memory T cells bearing CD3, CD4, human leukocyte antigen (HLA)-DR, CD25, and CD45RO. Eosinophils, basophils, and neutrophils are rarely present in acute AD. Mast cells are present in various stages of degranulation.

Chronic lichenified lesions are characterized by a hyperplastic epidermis with elongation of the rete ridges, prominent hyperkeratosis, and minimal spongiosis. There is an increased number of IgE-bearing dendritic cells (DC) in the epidermis, and macrophages dominate the dermal mononuclear cell infiltrate. The number of mast cells is increased but the cells do not generally show evidence of degranulation. Although intact eosinophils are hardly visible histologically, they are implicated in the dermis of chronic AD skin lesions since their products, such as eosinophil major basic protein, eosinophil cationic protein, and eosinophil-derived neurotoxin can be detected by immunostaining. Thus eosinophils likely contribute to allergic skin inflammation by the secretion of cytokines and mediators that augment allergic inflammation and may induce tissue injury in AD through the production of reactive oxygen intermediates and release of toxic granule proteins.

PATHOGENESIS

Much insight has been achieved into the pathogenesis of AD in recent years. We have learned that development of the chronic skin inflammation underlying both forms of dermatitis requires a combination of a

Fig. 44.2 Thickening of the epidermal compartment (acanthosis) with mild spongiosis. Lymphocytic and histiocytic inflammatory dermal infiltrate, mainly around the vessels.

genetically determined intrinsic defect of the epidermal barrier, immunological abnormalities, and environmental factors.

GENETICS

Parental atopy, in particular dermatitis, is significantly associated with the manifestation and severity of early AD in children.¹¹ Unexpectedly, other parental atopic diseases such as allergic asthma or allergic rhinitis seem to be a minor factor in the development of AD, suggesting the existence of genes specific to AD. Thus far, four genome-wide screens have aimed to identify the chromosomal regions where these genes could be located¹¹: several possible loci related to the AD clinical phenotype have been determined while the identification of the genes responsible is still awaited. The regions of strongest linkage were found on chromosomes 1q21 and 17q25, although contradictory results have been found for the latter one.¹²

Two paradoxical aspects remained to be clarified: (1) these regions correspond to gene loci found in patients with psoriasis, even though AD and psoriasis are clinically almost mutually exclusive; and (2) the chromosomal regions do not correspond to those previously reported for other atopic diseases such as allergic asthma.¹³

The other genetic approach is to screen variants, i.e., single nucleotide polymorphisms (SNPs), of candidate genes for possible association with the AD clinical phenotype (reviewed by Morar et al.¹¹). Several candidate genes have been identified in recent years, notably on chromosome 5q31-33, which contains genes for the Th2 cytokines interleukin (IL)-3, IL-4, IL-5, IL 13, and granulocyte-macrophage colony-stimulating factor (GM-CSF). Further studies have identified variants of the IL-13 coding region, functional mutations of the promoter region of the chemokine RANTES (17q11) and gain-of-function polymorphisms in the alpha subunit of the IL-4 receptor (16q12). Polymorphisms of the IL-4

subunit may have an influence on the IL-4-receptor-related synthesis of IgE. This could be linked to the incidence of nonatopic dermatitis, which occurs without any IgE sensitization. Similarly, a dysbalance between Th1 and Th2-immune responses in AD may be explained by polymorphisms of the IL-18-gene, resulting in a Th2 predominance. At a functional level, upon stimulation with superantigens, peripheral blood mononuclear cells (PBMC) from individuals with these polymorphisms respond with upregulation of IL-18 and downregulation of IL-12 and consequently show a Th2 predominance. A particularly severe course of AD with colonization of *S. aureus* may be associated with a SNP of the Toll-like receptor (TLR)-2 gene.

DISTURBED EPIDERMAL BARRIER FUNCTION

AD is characterized by dry skin affecting lesional and nonlesional skin areas. Altered skin barrier function, resulting in increased transepidermal water loss, is typical for this condition and may be, among others, an explanation for the facilitated penetration of allergens, bacteria, and viruses. The mechanisms behind this dryness are complex and closely related to the disturbed epidermal barrier function.¹⁴ The loss of skin ceramides, which serve as the major water-retaining molecules in the extracellular space of the cornified envelope, has been proposed to cause this modification of the skin barrier. Furthermore, variations of the stratum corneum pH may impair lipid metabolism in the skin. Overexpression of enzymes such as chymotrypsin is also likely to contribute to the breakdown of the AD epidermal barrier. Further considerations include a Δ -6-desaturase deficiency and a decreased conversion of ω -6-linoleic acids to prostaglandin in affected patients.

Recent studies underline the importance of a primary epithelial barrier defect in the pathogenesis of AD. Mutations of filaggrin (R510X and 2282del4), a key protein in terminal differentiation of the epidermis, seem to be important risk factors for AD and for AD in combination with asthma.¹⁵ The skin barrier may be impaired due to an alteration of keratin aggregation and hence permit the penetration of allergens, including high-molecular-weight aeroallergens.

IMMUNOLOGICAL MECHANISMS

As mentioned above, both a disturbed epidermal barrier and defects in the immune system are mandatory for the development of AD (Fig. 44.3). Having focused over the last three decades on the mechanisms directing adaptive immunity, mainly orchestrated by T and B cells for cellular and humoral immunity respectively, scientists have tended to overlook the significance of the so-called innate immunity¹⁶ (Chapter 3).

INNATE IMMUNITY

In recent years there has been a radical transformation of our understanding of how mammalian organisms respond to microbial exposure. The innate immune system is able to react promptly to almost all kinds of microbial colonization and onslaught, while it is also involved in the initiation of the more specific but slower mechanisms of the adaptive immune response. Epithelial cells of the skin and cells residing at the interface between our environment and our organism are the first line of defense in the innate immune system.¹⁷ They are equipped with highly conserved recognition structures, the so-called pattern recognition

Fig. 44.3 Immunologic progression of atopic dermatitis. (Modified from Leung DYM. Atopic dermatitis: new insights and opportunities for therapeutic intervention. J Allergy Clin Immunol 2000; 105: 860.)

receptors (PRRs) such as the TLRs, which were initially described in the fruit fly. These TLRs can bind a variety of microbial structures due to highly conserved microbial surface molecules, the pathogen-associated molecular patterns (PAMP). At least 10 different TLRs have been described so far in humans and are more or less specialized in binding bacterial or fungal cell walls or viral nucleic acids (DNA or RNA with so-called CpG motifs). Hence, TLRs represent putative therapeutic targets to alter or modulate the adhesion of microbes to epithelial cells.

The binding of microbial products to the cell surface of epithelial cells leads to cellular activation, ultimately resulting in the production of molecules with anti-microbial activity: the so-called AMPs.¹⁷ These belong to the family of defensins and cathelicidins. In human skin at least one cathelicidin (LL37) and three defensins, the human β -defensins 1, 2, and 3 (HBD1, HBD2, and HBD3) have been described.

In AD, skin is highly colonized by bacteria such as *Staphylococcus aureus*. Much attention has been focused on the putative role of the innate immune system and particularly of AMPs in the control of these bacteria as well as of viruses. Recently it has been shown that AMPs are downregulated in the skin of human atopic individuals, probably due to the particular inflammatory microclimate created by infiltrating cells and their cytokines. These mechanisms predispose AD patients to develop extensive herpes infections such as eczema herpeticum.¹⁸

ACQUIRED IMMUNITY

T cells and the Th1/Th2 concept

A predominant systemic Th2 dysbalance with increased IgE levels and eosinophilia is widely accepted in the pathogenesis of atopic diseases.¹⁹ The production of Th2 cytokines, notably IL-4, IL-5, and IL-13, can be detected in lesional and nonlesional skin during the acute phase of disease. IL-4 and IL-13 are implicated in the initial phase of tissue inflammation and in upregulating the expression of adhesion molecules on endothelial cells. IL-5 seems to increase the survival of eosinophils. A systemic eosinophilia and an increase of the eosinophilic cationic protein (ECP) are characteristic during high disease activity of AD.

However, although Th2 cytokines seem to be predominant in the acute phase of AD, they are less important during its chronic course. In chronic AD skin lesions an increase of interferon- γ (IFN- γ) and IL-12, as well as IL-5 and GM-CSF, could be detected, being characteristic for a Th1/Th0 dominance.

The maintenance of chronic AD involves the production of the Th1-like cytokines IL-12 and IL-18, as well as several remodeling-associated cytokines such as IL-11 and transforming growth factor (TGF)- β 1, expressed preferentially in chronic forms of the disease. Th-1-mediated cells seem to be responsible for apoptosis of cells, although their pathomechanisms are yet not fully understood. Clearly, a generalized Th2-deviated immune response is closely linked to the condition of AD but the skin disease itself is a biphasic inflammation with an initial Th2 phase, while the chronic phase involves Th0/Th1 cells. This biphasic pattern of T-cell activation has also been demonstrated in studies of allergen patch test skin reaction sites.²⁰ Twenty-four hours after allergen application to the skin, increased expression of IL-4 mRNA and protein is observed, after which IL-4 expression returns to baseline levels. In contrast, IFN- γ mRNA expression is not detected in 24-hour patch test lesions, but is strongly expressed at the 48–72-hour time points. Interestingly, the increased expression of IFN- γ mRNA in atopic patch

test lesions is preceded by a peak of IL-12 expression coinciding with the infiltration of macrophages and eosinophils.

A study using an animal model of AD examined ovalbumin-elicited allergic skin inflammation in mice with targeted deletions of the IL-4, IL-5, and IFN- γ cytokine genes to assess the role of these cytokines.²¹ Allergen-sensitized skin from IL-5 knockout mice had no detectable eosinophils and exhibited decreased epidermal and dermal thickening, whereas IL-4 knockout mice displayed normal thickening of the skin layers but had decreased eosinophils. Sensitized skin from IFN- γ knockout mice was characterized by reduced dermal thickening.

Tregs are a diverse and complex family of cells with regulatory activities that became the focus of interest in the field of transplantation or tumor immunology as well as in allergy, since they have the ability to suppress T-cells (TH1 and TH2)²² (Chapter 16). Special combinations of surface markers (CD25⁺/CD4⁺) as well as mutations of the nuclear factor Foxp3 are characteristic for these cells. It has been shown that mutations of Foxp3 result in hyper-IgE, food allergy, and dermatitis. In addition, staphylococcal superantigens can subvert the function of Tregs and may thereby augment skin inflammation (Fig. 44.4).²³

CYTOKINES AND CHEMOKINES

The defining characteristic of the atopic immune system is the expression of proinflammatory cytokines and chemokines.²⁴ Cytokines from resident cells (such as keratinocytes, mast cells, or DCs) bind to receptors on the vascular endothelium and activate cellular signaling. This results in an initiation of processes leading to the characteristic extravasation of inflammatory cells.

Several different chemokines have been implicated in the pathology of AD. Large amounts of chemokines such as MIP-4/CCL18, TARC/CCL17, PARC/CCL18, MDC/CCL22, and CCL1 seem to be involved in the development of acute and chronic skin manifestations. These chemokines play an important role in the amplification of allergic reactions to bacteria or allergens. C-C chemokines (MCP-4, RANTES, and eotaxin) contribute to the infiltration of macrophages, eosinophils, and T-cells into acute and chronic AD skin lesions. An increasing number of chemokines have been shown to be up- or downregulated in patients with AD but their exact role in the pathogenesis of AD is still not resolved.

DENDRITIC CELLS

DCs are highly specialized professional antigen-presenting cells (APCs) and are essential for allergen uptake and its presentation to T cells in the context of primary and secondary immune responses (Chapter 7). The role of DC in AD has been extensively discussed elsewhere.²⁵ Two types of DC have been found in lesional skin of AD: myeloid (mDC) and, to a much lesser extent, plasmacytoid DCs (pDC). LC and inflammatory dendritic epidermal cells (IDEC) both belong to the group of mDC and express the high-affinity receptor for IgE (Fc ϵ RI) in lesional skin, suggesting a complex regulatory mechanism related to atopic status. While LC are present in normal skin, IDEC are mainly detected in inflamed skin.

LC and IDEC play a central role in the uptake and presentation of antigens or allergens to Th1/Th2 cells and most probably also to Tregs. Interestingly, Fc ϵ RI-expression is detected on LC from normal skin during active flare-ups of other atopic diseases such as allergic asthma or rhinitis, while Fc ϵ RI⁺ IDEC are confined to lesional skin. Although it remains to be definitely proven, there is some *in vitro* evidence that LC play a less

Fig. 44.4 Mechanisms of staphylococcal superantigen action in atopic dermatitis. (Modified from Leung DYM. Atopic dermatitis: new insights and opportunities for therapeutic intervention. J Allergy Clin Immunol 2000; 105: 860, with permission from Elsevier.)

dominant role than expected initially in the initiation of the allergic immune response. Nevertheless, they are active in priming naïve T cells to become T cells of Th2 type and produce distinct chemokines such MCP-1 upon receptor ligation. In contrast, the stimulation of FcεRI on IDEC leads to a switch to Th1 response and to the release of high amounts of proinflammatory signals that amplify the allergic immune response. The atopy patch test can be used as an experimental model for AD – skin biopsies of such patch tests show that, 72 hours after allergen challenge, high numbers of IDEC invade the epidermis while alterations of the phenotype of LC and IDEC occur, including the upregulation of FcεRI.

Compared to ACD, the number of pDC is dramatically decreased in the skin of AD patients. pDC have been shown to play a major role in the defense against viral infections by producing type 1 interferons. A lower density of pDC might contribute to the susceptibility towards viral skin infections such as eczema herpeticum in these patients. In contrast to LC and IDEC, pDC seem to express FcεRI constitutively and this is upregulated in AD patients. Activation of this receptor leads to altered surface expression of major histocompatibility complex (MHC) molecules, enhanced apoptosis of pDC, and a decrease in the secretion of type I interferons.

MICROBIAL AGENTS

Staphylococcus aureus is the predominant skin microorganism in AD lesions and is found in over 90% of AD patients.²⁶ This high colonization rate is probably due to a defect in the production of AMP by atopic keratinocytes. Infections often provoke exacerbation or aggravation of lesional skin. *S. aureus*-derived enterotoxins have been shown to play an important role in the pathogenesis of AD.²⁷ Enterotoxins such as staphylococcal enterotoxin A (SEA), B (SEB), C (SEC), and D (SED) are frequently detected in patients and might provoke sensitization. Moreover, since *S. aureus* enterotoxins act as superantigens, they interact directly

with the MHC-T-cell complex on APC and provoke antigen-independent proliferation of T cells. This results in an amplification of the inflammation and may lead to typical eczematoid skin reactions of AD patients. Specific IgE antibodies directed against staphylococcal superantigens can be detected in most AD patients, correlating with their skin disease severity.

It has been shown that binding of *S. aureus* to the skin is significantly enhanced by AD skin inflammation. An altered composition of fibrin and fibrinogen of AD skin is thought to be responsible. Scratching may enhance *S. aureus* binding by disturbing the skin barrier. *S. aureus* isolated from AD patients possesses increased ceramidase activity, which may be responsible for damaging the skin barrier.

AUTOALLERGENS

The majority of sera from patients with severe AD contain IgE antibodies directed against human proteins.²⁸ One of these IgE-reactive autoantigens is a 55-kDa cytoplasmic protein from skin keratinocytes; it has been cloned from a human epithelial cDNA expression library and designated *Hom s 1*.²⁹ Although the autoallergens characterized to date have mainly been intracellular proteins, some have been detected in IgE immune complexes in sera of sensitized patients, suggesting that release of these autoallergens from damaged keratinocytes due to scratching could trigger IgE- or T-cell-mediated responses. A more recent study has shown that the emergence of IgE against self proteins can be detected as early as 1 year of age.³⁰ These data suggest that, while IgE immune responses are initiated by environmental allergens in combination with skin inflammation, allergic inflammation can be maintained by human endogenous antigens in patients with severe AD. Thus, if the assumed pathophysiological role of these antibodies holds true, AD should be considered as a disease at the boundary between allergy and autoimmunity.

■ NONATOPIC AND ATOPIC DERMATITIS IN THE CONTEXT OF THE NATURAL HISTORY OF ATOPIC DERMATITIS ■

As mentioned above, the new definition of AD requires the presence of IgE-mediated sensitization. However, this would imply that *nonatopic dermatitis* and *AD* represent two different diseases. Since dry skin is an important clinical sign of both conditions and is considered as a cardinal sign in atopic individuals as well, there is a great need for new concepts that reconcile these diverging ideas. Based on most recent genetic and immunological findings, a new picture emerges in which the natural history of AD seems to be divided into three phases: (1) an initial phase representing nonatopic dermatitis occurring in early infancy before any sensitization has taken place. This is then followed in 60–80% of cases by (2) sensitization to food and/or environmental allergens with the development of true AD (according to the new definition). In this phase, it is speculated that FcεRI⁺ DC play a major role in controlling the inflammation. Consequently, these AD patients will benefit from allergen avoidance measures. Finally, (3) probably due to scratching, tissue damage, and molecular mimicry, an IgE sensitization to self proteins is observed in about 25% of AD patients. Whether these specific IgE have a pathophysiological role or are just an epiphenomenon remains to be clarified. According to this concept, sensitization could be influenced by the intensity of skin inflammation, which would be in accord with the concept of the atopic march. Furthermore, attempts to control skin inflammation effectively as early as possible would putatively help to hamper the degree of subsequent sensitization.

■ MANAGEMENT OF ATOPIC DERMATITIS ■

The management of AD can be established on five main axes and must be adapted to the severity of the lesions: (1) skin care to restore and preserve the epidermal barrier function; (2) recognition and elimination of the provocation factors; (3) control of (even subclinical) inflammation and pruritus; (4) reduction of microbial colonization; and (5) education of patients and their parents. Throughout, topical treatment is preferred to systemic therapy, which should be reserved for the most severe forms. Successful management thus requires a multifaceted approach, and it is stressed that education of the patient is as important as pharmacological strategies.

SKIN CARE

A key feature of AD is severe dryness of the skin due to a dysfunction of the skin barrier with increased transepidermal water loss. The regular use of emollients and skin hydration is essential to improve dryness, to prevent intense pruritus, and to control subclinical inflammation during periods of remission. The choice of emollients depends on the individual skin status. Water-in-oil or oil-in-water emulsions may be substituted to support the skin barrier function. Urea allows an intensive hydration of the skin while salicylic acid can be added to an emollient for the treatment of chronic hyperkeratotic lesions.

Irritants such as soaps, clothing made from occluding or irritating, synthetic or wool material, and hot water temperature should be avoided or reduced to a minimum.

ELIMINATION OF PROVOCATION FACTORS

The patient should be educated adequately to avoid provoking factors. Specific provocation factors, such as airborne and food allergens, have to be considered and identified by serum tests for allergen-specific IgE or skin prick tests. Because of the putative role of food allergens in children, diets directed by allergological tests can be of interest but blind extensive diets, which can be nutritionally deficient, are useless. Sensitized patients should avoid house dust mites; this may include use of house dust mite-proof encasings on pillows, mattresses, and box springs. Whether patients sensitized to animal dander should be discouraged from keeping household pets is still a matter of debate.

In selected patients hospitalization may be of great benefit, especially in centers using a multidisciplinary team approach.

Food hypersensitivity affects 10–40% of children with AD. In children 90% of reactions are caused by only five allergens: eggs, milk, peanuts, soy, and wheat. Dietary restriction is only of value in patients whose allergies have been properly diagnosed, though any exclusion diets should be properly supervised by a pediatric dietician to ensure adequate nutrition. Hydrolyzed cow's-milk formula consisting of predigested peptides of whey and cytokine can be useful as its nutritional values are equivalent to normal milk, but it has a reduced capacity to induce IgE-mediated reactions.

CONTROL OF INFLAMMATION

Topical glucocorticosteroids

Topical steroids are safe and effective when used properly. Anxiety among both the general public and family physicians is often well out of proportion to the true risk. Aside from their anti-inflammatory effect, topical steroids contribute to a reduction of skin colonization with *S. aureus*. The strength and mode of application depend on disease activity and severity, the locations to be treated, and the age of the patient. Only mild to moderately potent preparations should be used on facial, genital, or intertriginous skin areas. Less potent topical steroids should be used in children less than 1 year old. The application of steroids should be limited to short courses of about 2 weeks, no more than twice a day. New steroid preparations and application protocols have reduced the risk of adverse effects and are effective when applied once daily. A number of different therapeutic schemes have been proposed: the initial treatment of acute phase can be with moderate- to high-potency steroids followed by a dose reduction or an exchange to a lower-potency preparation. However, our own experience has shown better compliance by tapering off the use of the same mid-potent topical steroid over several weeks. Intermittent use of topical steroids once or twice a week on areas prone to flare-up has been proven to reduce flares for up to 6 months, with increased compliance and better overall disease control.³¹ Treatment with emollients is important both during the course of steroid treatment and as part of long-term management.

Topical calcineurin inhibitors

Pimecrolimus and tacrolimus are immunosuppressive compounds that inhibit a calcium-activated phosphatase called calcineurin. They suppress the early phase of T-cell activation, degranulation of mast cells, and the expression of various cytokines required to activate cellular immunity. In contrast to topical steroids, which induce apoptosis of T cells and DC in the treated epidermis of patients with AD, calcineurin inhibitors do not affect LC numbers or function but effectively repress IDEC.³²

The anti-inflammatory activity of tacrolimus and pimecrolimus is similar to a corticosteroid of moderate to strong potency.³³ Pimecrolimus cream (1%) and tacrolimus ointment (0.03%) are available for treatment of children 2 years of age and older. Tacrolimus ointment (0.1%) is only approved for use in adults. Side effects such as dermal atrophy or teleangiectasia are not seen, which therefore makes treatment of the face possible. Postmarketing surveillance of several million treated patients has not identified any particular problems as long as the drugs are used under medical supervision. Nevertheless some authors have suggested that the period of continuous treatment should be limited to 1 year with pimecrolimus and to 4 years with tacrolimus. However, there is no clear rationale for that opinion and, in routine daily practice, patients never use anti-inflammatory treatment on a continuous daily basis for longer periods of time.

Side effects include a transient burning sensation of the skin. While using calcineurin inhibitors, patients should avoid excessive exposure to natural or artificial sunlight (tanning beds or ultraviolet (UV) A/B treatment). Long-term safety studies analyzing a possible causal link between the topical use of calcineurin inhibitors and cancer as well as an increased incidence of viral infections are ongoing. Based on some caveats, the US Food and Drug Administration and the European Agency for the Evaluation of Medicinal Products have issued some warnings concerning the use of topical calcineurin inhibitors and have advised their use as second-line treatment. Continuous long-term use is not recommended until the long-term safety profile has been definitely confirmed.

Control of pruritus

Itch is often the most troublesome symptom for patients and is difficult to treat. Currently there is no specific anti-pruritic treatment except local applications of anti-inflammatory preparations and emollients. H₁-receptor antagonists (alimemazine and promethazine) are predominantly used for their sedative effect and are given 1 hour before bedtime. Most studies conclude that nonsedating antihistamines have little or no value in AD. In fact, the most effective control of pruritus is still provided by an effective anti-inflammatory regimen.

Reduction of microbial colonization

As mentioned above, both the affected and nonaffected skin of AD patients is heavily colonized with *S. aureus*. Even in the absence of exudation and pustule formation, which imply a superinfection, topical antiseptics with a low sensitizing potential such as triclosan or chlorhexidine can be used since they show low resistance rates. If an antibiotic is needed to treat infection, fusidic acid is the agent of choice, due to high resistance rates of *S. aureus* to erythromycin. Topical fusidic acid has been proven to be very effective against *S. aureus* because of its low minimal inhibitory concentration and good tissue penetration. However, long-term therapy with fusidic acid is not appropriate due to increasing

resistance rates, and therapy should be restricted to 2 weeks. Intranasal eradication of methicillin-resistant *S. aureus*, frequently found in AD patients, can be achieved by the topical use of mupirocin.

When widespread bacterial secondary superinfection (primarily *S. aureus*) occurs, systemic antibiotic treatment is indicated. A short-course treatment (3–7 days) with cephalosporins (cephalexin) or semisynthetic penicillins (floxacin or amoxicillin-clavulanate) has been shown to be effective. Due to the high frequency of resistance, erythromycin is less useful. In drug-allergic patients, clindamycin or fusidic acid are possible alternatives.

MANAGING SEVERE FORMS OF AD

It is well accepted that, in severe cases of AD, topical treatment alone will not allow sufficient control of the condition. In these cases, systemic therapy is indicated, at least for a limited period of time until topical regiment can be resumed.

Systemic corticosteroids

Oral corticosteroids have a limited but definite role in the treatment of severe exacerbations of AD. A brief course may be used to control severe disease, but ongoing use of systemic corticosteroids carries significant adverse effects. After discontinuation of oral steroids, severe relapses may occur, but data from randomized clinical trials are lacking.

Cyclosporine A

Cyclosporine A (CyA) inhibits calcineurin-dependent pathways, resulting in reduced levels of proinflammatory cytokines. The ongoing use of systemic immunosuppressive agents such as CyA should be reserved for very severe cases of disease, not responding to other measures. Despite its side effects, especially renal toxicity with hypertension and renal impairment, multiple studies have shown a beneficial effect of CyA in children and adults. Close monitoring of creatinine and CyA serum levels is essential. Exacerbation can occur after discontinuation, but posttreatment disease severity often does not return to baseline levels.³⁴ Treatment regimes are adjusted to body weight, with 3–5 mg/kg per day for a high-dose regime or 2.5 mg/kg per day as low-dose treatment. In order to minimize side effects, the lowest effective dose should be used. In children it should be remembered that vaccinations may not be effective while under immunosuppression.

Mycophenolate mofetil

Mycophenolate mofetil is an immunosuppressive purine biosynthesis inhibitor used for the treatment of moderate to severe AD.³⁵ The drug is generally well tolerated when given as short-term oral treatment with 2 g/day. After 5 weeks the dosage can be reduced to 1 g/day and continued for another 3 weeks. Occasional herpes retinitis has been recorded and should be watched for and treated appropriately.

Azathioprine

Azathioprine is another immunosuppressant drug used to treat severe AD. It affects purine nucleotide synthesis and metabolism and has both anti-inflammatory and anti-proliferative effects. Controlled trials have

not been reported; side effects are common, including myelosuppression, hepatotoxicity, gastrointestinal disturbances, increased susceptibility for infections, and possible development of skin cancer. As azathioprine is metabolized by thiopurine methyltransferase, a deficiency of this enzyme should be excluded before starting oral immunosuppression with azathioprine.³⁶

Phototherapy

UVB (280–320 nm), narrow-band UVB (311–313 nm), UVA (320–400 nm), medium- and high-dose UVA₁ (340–400 nm), and psoralen UVA (PUVA) have all undergone trials for the treatment of AD.³⁷ UVA₁ irradiation seems to be superior to conventional UVA–UVB phototherapy in patients with severe AD, and has become established as a standard second-line treatment for adults with or without additional topical or systemic treatment. The use of UV therapy in children should be restricted since data about long-term side effects of UV therapy (e.g., skin cancer) are still not available. Bearing in mind a possible link between UV irradiation and photo-aging, skin carcinogenesis, or melanoma induction, the duration of therapy should be limited to about 4–6 weeks.

Immunotherapy

In older studies, no benefit could be shown from allergen-specific desensitization in AD. These findings have also suggested over years that AD is if anything a contraindication for immunotherapy. More recent studies using specific immunotherapy in AD patients sensitized to house dust mite (*Dermatophagoides pteronyssinus*) have led us to revise this opinion.³⁸ Further studies are now ongoing in order to validate this concept. Another promising area of study is the use of sublingual immunotherapy (SLIT), which has been established as efficient in rhinitis and asthma.³⁹ SLIT could represent a useful alternative to injections, especially for children, but proof of efficacy in AD is still awaited.

Biologicals

In the last few years, advances in immunopharmacology have provided clinicians with new molecules developed to interfere with molecular mechanisms such as cytokine–receptor interactions: the resulting biologicals represent a breakthrough in the management of chronic diseases. Although patients suffering from severe psoriasis, another chronic inflammatory skin disease,⁴⁰ have greatly benefited from biologicals, AD patients are still awaiting a similar gift. Only few reports about the use of such molecules are available but no clinical trials have been completed so far. Apart from some individual case reports, it remains to be determined whether omalizumab, an anti-IgE monoclonal antibody, will offer any advance in the management of severe forms of AD, although the high levels of circulating IgE in these patients will tend to limit its applicability.

EDUCATION OF PATIENTS WITH ATOPIC DERMATITIS

Patient education has proven to be of great benefit in the management of AD, especially for young patients and their parents. Knowledge about the disease and its therapeutic strategies lead to a higher level of

THERAPEUTIC PRINCIPLES

MANAGEMENT OF ATOPIC DERMATITIS

Principles and tools

1. Skin care to restore and preserve the epidermal barrier function
 - >> Individually adapted emollients and/or ointments with or without urea
2. Recognize and eliminate the provocation factors
 - >> Allergological diagnostic, food allergens and aeroallergens, encasing
3. Control of skin inflammation and pruritus
 - >> Topical steroids (first-line), topical calcineurin inhibitors
 - >> Phototherapy
 - >> Antihistamines
 - >> Systemic steroids, immunosuppressive agents (cyclosporine A, azathioprine, mycophenolate mofetil)
 - >> Specific immunotherapy
 - >> Biologicals
4. Reduce microbial colonization
 - >> Topical antiseptics
 - >> Systemic antibiotics only in severely infected cases
5. Education
 - >> Need for early intervention
 - >> Atopic dermatitis educational programs, atopic dermatitis schools

compliance as well as psychological stability. The acceptance of the disease and its chronic course by the patient and those around the patient significantly improves their quality of life. Furthermore, the new strategy of early intervention aiming to control skin inflammation at an early stage, in the hope of hampering further sensitization mechanisms, needs the full acceptance and compliance of the parents. Adequate educational programs are additionally effective when offered in a multidisciplinary context, with dermatologists, pediatricians, dieticians, psychologists, and nursing staff working with patients and their families.

FUTURE PERSPECTIVES

We are currently experiencing a new and fascinating phase in AD research. Combining data from epidemiology, genetics, skin physiology, immunology, and allergy provides new areas of research that will certainly offer new perspectives and new concepts in the pathophysiology and management of this disease. The role of innate immunity has been underestimated over years but is now the subject of numerous projects, and functional genetics will help us to understand better the consequences of so many genetic variants in candidate genes. Together these will hopefully lead to the development of new biologics but also

new antagonist molecules based on small-molecular-weight compounds, steroid analogues, and other treatments that are or will be in the pipeline over the next few years. Finally, beside these new pharmacological approaches, one of the most important aspects remains the strategy of very early treatment of young children by controlling skin inflammation at the earliest practical time point. This strategy may help us better control the emergence of sensitization and provide a rapid and hopefully definitive cure of the disease. If successful, physicians would be able to provide a convincing disease-modifying strategy for AD patients.

■ ALLERGIC CONTACT DERMATITIS ■

DEFINITION

Contact dermatitis is an eczematous skin eruption caused by local exposure to allergic sensitizer or irritant/toxic substances. These include immunologic, chemical, protein, or physical agents but infectious agents are excluded. Contact dermatitis is a common cause of morbidity with a life prevalence of 15% and incidence of more than 7.9 per 1000. However, the sensitization rate is higher than this – studies in Scandinavia have shown that 15–20% of the population displays at least one positive patch test reaction to contact sensitizers. In the USA, occupationally related contact dermatitis is estimated to cost \$250 million per year in lost productivity, medical care, and disability payments.

PATHOPHYSIOLOGY

Genetics

ACD is a multifactorial condition in which genetic background plays an important part, as shown by twin and family studies. In case-control studies, SNPs in certain enzymes such as NAT2 (*N*-acetyltransferase) or the promoter region of IL-16 have been associated with multiple sensitization status.^{41,42}

Histology

The histological hallmark of ACD is intercellular edema or spongiosis, accompanied by a mixed inflammatory cell infiltrate around dermal vessels; eosinophils may be especially prominent in the initial acute phase. As ACD becomes chronic, the degree of spongiosis decreases while epidermal hyperplasia increases. This is seen macroscopically as lichenification.

The allergens

Most contact allergens are haptens, i.e., simple chemicals that bind to proteins (carrier) present in skin to form a complete antigen. The key to understanding the pathogenesis of contact allergy is an appreciation of the discriminate nature by which chemicals can serve as antigens (Chapter 6). Clearly, not all chemicals act as allergens. To be allergenic, the chemical must be able to penetrate the principal barrier in skin (the stratum corneum) and reach the living cells of the epidermis. Only molecules with molecular mass less than 500 Da are capable of penetrating the stratum corneum, and so most contact allergens are low-

Table 44.1 Most common contact allergens (listed in approximate order of decreasing frequency)

1. Nickel sulfate	Nickel-plated objects are omnipresent. Jewelry that looks like gold or silver has nickel in it. Gold greater than 18 carats is safe; so is aluminum; stainless steel contains nickel but it is not releasable
2. Fragrance mix	Anything that smells good has fragrance chemicals in it (e.g., cinnamates, vanillin, oak moss, eugenol, geraniol). Also used as flavorings
3. <i>P</i> -phenyldiamine	Preservative used in vaccines, antitoxins, eye and nasal medications
4. Chromate	Sensitizer in wet cement. Used as an oxidizing agent and for its anticorrosion properties. Found in glues and adhesives, leather, paints, matches, detergents, and bleaches
5. Methyl dibromoglutaronitril/phenoxymethanol (MDBGN/PE)	Preservatives, antimicrobial and industrial biocides
6. Thiuram mix	Rubber accelerator and vulcanizer. Fungicide and animal repellent. Also found in lubricating oils. Cross-reacts with disulfiram
7. Methylchloroisothiazolinon/methylisothiazolinon (Kathon CG)	Preservative in paints, glues, and cosmetics
8. Formaldehyde	Preservative found in cosmetic products and topical medications. Sterilizer in cleaning agents. Fixative for tissues. Tanning agent for leather. Hardener for fabrics. Fumigant, fungicide, and insecticide
9. Parabens	Used as sunscreen agent and preservative in cosmetic products

molecular-weight compounds. Lipid solubility promotes transit through the stratum corneum. Thus, most contact allergens are small, lipophilic molecules. The most common of these chemicals are listed in Table 44.1. Once in the epidermis, the nature of the protein carrier for the hapten is very important because if the contact sensitizer is complexed to nonimmunogenic carriers, this may induce tolerance rather than sensitization.⁴³

THE SENSITIZATION PHASE

The pathophysiology of ACD has been extensively reviewed elsewhere.⁴⁴ The principal event during sensitization is presentation of antigen to responder T cells by APC, culminating in activation and differentiation of T cells that proliferate in an antigen-specific clonal manner. LC are the principal APCs within the epidermis and are generally thought to be responsible for presentation of contact allergens in the primary (sensitization) phase as well as in the secondary (elicitation) phase of the immune response. However, recent studies in LC knockout animal models have seriously challenged this view.⁴⁵ Other DCs in skin, especially in the dermis, may also serve as APCs for contact allergens, including LC precursors, and dermal DCs, while macrophages may be important in the elicitation phase.

The clinical outcome of each exposure to antigen depends upon several factors. First and foremost is the integrity of the stratum corneum. An injured or diseased stratum corneum that allows greater penetration of exogenous substances will increase the chances of activating APCs in the skin. A second factor is the viability of APCs in skin, since these cells need to seek and bind appropriate responder T cells. Third is the presence or absence of extracellular factors, including cytokines produced by keratinocytes that can promote or hinder APC-T-cell engagement. The final factor is the pre-existing mix of T-cell subtypes specific for the antigen. The higher the frequency of cells of an effector subtype, the higher the likelihood that dermatitis will result, whereas a higher frequency of cells of a regulatory subtype may limit or prevent the development of dermatitis.

THE ELICITATION PHASE

The elicitation or efferent phase is characterized by invasion of the skin by antigen-specific memory T cells as well as other inflammatory cells, producing what is clinically recognized as ACD. Memory T cells and other inflammatory cells leave vessels and enter the skin through sequential activation of a number of adhesion molecules by cytokines. Memory T cells constitutively express cutaneous lymphocyte antigen (CLA). E-selectin, the ligand for CLA, is induced on vascular endothelium by inflammatory mediators such as IL-1 and tumor necrosis factor- α (TNF- α). This interaction causes memory T cells to slow down and roll along the endothelial surface as a prelude to migration to sites of inflammation. Firm adhesion and migration of leukocytes to the endothelium are mediated by T-cell VLA-4/LFA-1 and endothelial cell VCAM-1/ICAM-1, respectively. Subsequently, LFA-1⁺ T cells migrate toward ICAM-1⁺ epidermal cells.

Mast cells may also participate in the elicitation phase. In mice, mast cells can be activated by a T-cell-derived antigen-binding factor that induces release of serotonin, producing swelling 2 hours after challenge. In addition, mast cells contain preformed TNF- α , which may regulate the adhesion molecules involved in the early recruitment of helper T cells.⁴⁶

The net result is an influx of T cells secreting IL-2 and IFN- γ into the area of allergen exposure. These cytokines enhance the immune response through activation and recruitment of more inflammatory cells, producing spongiosis and the inflammatory dermal infiltrate characteristic of ACD.

CLINICAL MANIFESTATIONS (FIG. 44.5)

As a rule, ACD takes several hours, days, or even weeks to develop, while irritant contact dermatitis may manifest within minutes to hours of contact, especially when due to strong agents. If left alone, most cases of contact dermatitis resolve completely. Unfortunately, this ideal situation is almost never realized because the accompanying itch results in scratching and attempts at topical treatment, which in turn lead to spread of the dermatitis, often with superimposed bacterial or dermatophytic infection. These and the effects of partial but incomplete treatment can produce diagnostic confusion.

The intensity of the dermatitis depends on the concentration of the inciting chemical and, in the case of ACD, on the sensitivity of the

Fig. 44.5 Allergic contact dermatitis.

individual to the allergen. Acute inflammation is expressed as erythema, blistering, oozing, and crusting; rarely frank necrosis may ensue. Subacute inflammation manifests as erythema, scaling, fissuring, or a parched, scalded appearance. Chronic inflammation may have less erythema, but the skin becomes thickened with lichenification and excoriation. Itching is a cardinal feature of contact dermatitis, regardless of severity. The keys to diagnosis are recognition of the eczematous nature of the skin eruption and correlation of the pattern and distribution of the lesions to the shape of the offending substance or the nature of exposure to it.

The location of the dermatitis also serves as an important clue to the source of the offending chemical (Table 44.2). Although ACD usually affects the site of principal exposure, it can spread to other more distant sites, either by inadvertent contact or by autosensitization. Furthermore, the scalp, palms, and soles are relatively resistant to ACD and may not exhibit pathology, while surrounding areas are severely affected. A geographic approach can be very helpful in identifying the causal allergen. Although the typical presentation is eczematous, contact dermatitis may occasionally present as urticaria (contact urticaria), altered pigmentation (either hyperpigmentation or hypopigmentation), erythema multiforme, or even purpura (usually on the legs). Widespread involvement, particularly of the face and of body areas unprotected by clothing, should raise suspicions of contact dermatitis produced by airborne allergens such as plant pollen, sprays, or fumes. Photocontact dermatitis can also have a similar diffuse presentation. Rarely, contact dermatitis may become generalized, presenting as exfoliative erythroderma. In some cases ACD can be induced by body contact (e.g., to perfumes or cosmetics).

Table 44.2 Common causes of contact dermatitis by location

Scalp	Shampoos, hair dyes
Ears	Metal earrings, eyeglasses, hair care products
Eyelids	Nail polish, cosmetics, contact lens solution, airborne allergens
Face	Cosmetics, other topical preparations, including sunscreens, airborne allergens
Neck	Necklaces, perfumes, airborne allergens
Trunk	Topical preparations, clothing, including metal components and elastic in undergarments
Axillae	Deodorants, clothing
Hands	Soaps and detergents, occupational chemicals, metals, including jewelry, topical preparations, rubber gloves
Genitals	Topical preparations, condoms
Anal region	Fecal spillage, topical preparations
Legs	Topical preparations, elastic in socks
Feet	Rubber, leather, or synthetic materials in shoes.

ACD can occur at any age, but it is less frequently seen in the very old or very young. Older individuals have been shown to have various defects in the induction and/or elicitation of ACD. Children also tend to have fewer episodes of ACD but, in contrast to the elderly, this is probably due to limited exposure rather than deficient immunity. When ACD occurs in children, it is typically in older pediatric patients. The most common causes include poison ivy, nickel (jewelry), rubber (shoes), fragrance, formaldehyde (cosmetics and shampoo) and neomycin (topical antibiotics). In adults the most likely sources of ACD are allergens peculiar to the individual's occupation or hobbies.

MANAGEMENT OF ACD

Diagnosis

The clinical and histological findings of ACD are characteristic, but not diagnostic. The most widely available method for confirming the diagnosis of ACD is patch testing. Patch tests are especially indicated in cases characterized by recurrent episodes of ACD, in cases in which there is a need to identify the offending allergen, and in cases recalcitrant to conventional therapy. Patch tests document the presence of delayed-type hypersensitivity; results are usually read at 48 and 96 hours after placement of the allergens. Systemic immunosuppressive agents (e.g., systemic corticosteroids, cyclosporine, and azathioprine) or sunbathing can suppress T-cell-driven responses, and a 2–3-week washout period is advisable prior to performing patch tests in patients treated with these drugs.

The results of patch tests must be interpreted in the context of the patient's experience and exposure. A positive result does not definitively identify the cause of the ACD. False positives may be due to an irritant (rather than an allergic) effect. In these cases, patch testing in control individuals can be of great value. False negatives can occur because patch testing does not reproduce the actual environment in which the allergen is encountered. Failure to perform a second reading (between 4 and 7 days after allergen placement) may mean that late positive results are missed. Finally, only a limited number of chemicals may be tested, and although most series of allergens include the most common causes of ACD, they will not include all possible allergens. Thus a negative patch test may simply mean that the relevant allergen was not tested. Equally, some cases of contact dermatitis are due to irritants rather than to allergic sensitizers. Usually it will be clear from the history if irritant materials are being used, but if the patch tests are negative it is worth going back over the history with the patient to see whether any irritant exposures have been overlooked.

Allergen avoidance

The most important aspect of managing patients with ACD is to identify correctly the cause and provide instructions about avoiding further contact with the allergen(s). Many allergens cross-react with other compounds and thus patients should be informed of this possibility.

Symptomatic therapy

Acute forms of contact dermatitis, particularly those involving greater than 10% of the total body surface, respond well to systemic corticosteroid treatment. Topical therapy may suffice for less acute or less widespread forms of contact dermatitis.

Cold, wet compresses are highly effective during the acute blistering and oozing stage; they should be used for 15–30 minutes several times a day for 1–3 days until blistering and severe itching are controlled. Short, cool tub baths, especially with colloidal oatmeal, are soothing and help to control the acute inflammation. Antihistamine agents are not usually helpful.

Short courses of corticosteroids over 2–3 weeks are the definitive treatment. As mentioned previously, acute dermatitis and widespread involvement require systemic administration (e.g. oral prednisone, initially at a maximum dose of 1 mg/kg, tapered over at least 2 weeks). Less acute or less widespread dermatitis responds well to topical corticosteroids, the strength of which should be tailored to the age of the patient and the body part involved. For example, 1–2% hydrocortisone cream or lotions may be used in infants or on the face and mucous membranes of adults, whereas higher-potency corticosteroids like 0.1% triamcinolone cream may be used on other areas. As a rule, lotions and creams work best in the acute and subacute phases while ointments should be reserved for chronic and lichenified lesions.

CONCLUSION

ACD is a delayed-type, T-cell-mediated response following exposure to chemical sensitizers. The role of epidermal LC in the induction of ACD has recently been questioned and they may be more involved in inducing tolerance, while dermal DCs and other APC seem to play a more important role than previously believed. Irritant contact dermatitis has a similar histology, but does not involve specific sensitization.

Patch testing is the procedure of choice to confirm the diagnosis of ACD and to identify the offending contact allergens. Despite international standardization, there are still concerns about the reproducibility of patch tests and their interpretation requires both experience and judgment. The keys to management are prevention by avoiding substances containing the allergens that have been identified, and the administration of topical and/or systemic corticosteroids to get rid of any ongoing dermatitis.

Food allergy

Scott H. Sicherer

45

Adverse reactions to foods can result from immunologic (*food allergy*) and nonimmunologic responses.^{1,2} More than one in five persons alters their diet for a presumed food allergy, but nonimmune causes can often be identified.³ Toxins or pharmacologically active components of the diet account for a number of nonimmune adverse reactions. Recently, the term *hypersensitivity* has been applied to an exaggerated response to any food component, even a nonimmune reaction.¹ Therefore, lactose intolerance, resulting in abdominal discomfort due to a reduced ability to digest lactose, may be defined as *nonallergic hypersensitivity*. Examples of adverse reactions to foods are shown in Table 45.1. Immune responses to foods are a normal phenomenon, leading to a state of oral tolerance.⁴ In contrast, aberrant immune responses to food proteins can lead to a variety of symptoms and disorders, defined together as food allergies.⁵ It is conceptually and diagnostically helpful to divide food allergic disorders broadly by immunopathology, into those that are associated with detectable food-specific IgE antibodies and those that are not.⁶ Disorders with an acute onset of symptoms following ingestion are typically mediated by IgE antibodies. Food-specific IgE antibodies arm tissue mast cells and blood basophils, a state termed *sensitization*. Upon re-exposure, the causal food proteins bind to the specific IgE antibodies and may trigger the release of mediators such as histamine, causing symptoms that may affect the skin, gastrointestinal tract, respiratory tract and cardiovascular system (Chapter 42). Another group of food allergic disorders, affecting primarily the gastrointestinal tract, are subacute or chronic and mediated primarily by T cells. A third group of chronic disorders that may be associated with food allergy, atopic dermatitis and eosinophilic gastrointestinal disorders, are variably associated with detectable IgE antibody (IgE associated/cell-mediated disorders).

children and 3.7% of adults in the USA have a food allergy. In young children, the most common causal foods are cow's milk (2.5%), egg (1.3%), peanut (0.8%), wheat (~0.4%), soy (~0.4%), tree nuts such as walnut and cashew (0.2%), fish (0.1%) and shellfish (0.1%). Studies in the USA and UK have indicated at least a doubling in the rate of peanut allergy in young children during the past decade.^{7,8} It is not known whether this trend is exclusive to peanuts. Studies have not implicated maternal diet as a factor, but noningestion exposures such as skin contact have been implicated as a route of sensitization.⁹ Adults rarely (< 0.3%) have allergies to milk, egg, soy or wheat, and are more commonly allergic to shellfish (2%), peanut (0.6%), tree nuts (0.5%), and fish (0.4%).³ Virtually all foods can cause an allergy in at least some individuals.¹⁰ Reactions to fruits and vegetables are particularly common (~5%) but usually not severe, whereas reactions to seeds (e.g., sesame, poppy) are being reported with increasing frequency and can be severe. Allergy to additives and preservatives, though often suspected, are uncommon (< 1%).¹¹ Genetic risk factors for food allergy include a family or personal history of atopic disorders (asthma, atopic dermatitis, allergic rhinitis, food allergy).

The influence of food allergy on specific disease states varies according to the type of disease and the age group affected.² Anaphylaxis in the community setting is attributed to food allergy in 35–55% of episodes: common offenders are peanuts, nuts, and seafood. Food allergy is also a common cause of acute urticaria (20%) and is associated with atopic dermatitis in nearly 40% of children with mild to moderate disease, most commonly with milk and egg allergy. In contrast, food allergy is not a common cause of chronic isolated respiratory symptoms, chronic urticaria, or atopic dermatitis in adults.

PREVALENCE

Perceived food allergies are often not verified when standardized procedures, such as double-blind, placebo-controlled oral food challenges, are undertaken.² Estimated rates of food allergy, and the specific causal foods, vary by age and geographic region, and are influenced by factors such as regional diets, environmental exposures such as pollen, and the fact that many food allergies resolve in childhood.³ It is estimated that 6% of young

CLINICAL MANIFESTATIONS

The clinical manifestations of food allergy are diverse and result from the underlying immune mechanisms and their impact on particular target organs.^{3,5,12} Food allergy can present as an acute reaction following ingestion of a causal food, with a sudden onset of typical symptoms such as hives or respiratory compromise; as an increase in chronic symptoms such as exacerbation of atopic dermatitis; or as a chronic disease. Where symptoms

Table 45.1 Examples of adverse reactions to foods

Intolerance (nonallergic hypersensitivity)
Lactose intolerance (lactase deficiency)
Sucrase–isomaltase deficiency
Galactosemia
Alcohol
Caffeine (jitteriness)
Tyramine in aged cheeses (migraine)
Toxins
Bacterial food poisoning
Scombroid (in dark-meat fish, may mimic allergy)
Food allergy (immune responses)
IgE-mediated
Not IgE-associated
Mixed IgE/non-IgE (eosinophilic gastrointestinal disease, atopic dermatitis)
Neurologic and psychological/psychiatric
Auriculotemporal syndrome (facial flush with salivation)
Gustatory rhinitis
Anorexia nervosa and food aversions

*The revised nomenclature of the World Allergy Organization uses the term ‘hypersensitivity’ to indicate a reproducible symptom or sign to a stimulus tolerated at the same dose by normal persons apart from an immunologic basis (e.g., lactose intolerance would be termed a nonallergic hypersensitivity).

are compatible with one of these patterns, a food allergy should be considered in the differential diagnosis. Specific disorders are summarized in Table 45.2. Disorders and symptoms such as behavioral problems, arthritis, and headache have not been convincingly or commonly linked to food allergy. Reflux, infantile colic and recalcitrant constipation have been attributed to food allergy in a subset of pediatric patients.

IGE-ASSOCIATED FOOD ALLERGIES

A typical feature of IgE-mediated food-allergic reactions is the timing of symptoms: reactions typically occur within minutes, and rarely more than an hour, after the ingestion of a triggering food. The organ system/ systems affected and the specific symptoms additionally define these reactions. *Urticaria and/or angioedema*, pruritus and flushing are common skin manifestations of food allergy, either alone or in combination with other symptoms. The rash may occur anywhere, although the face is most commonly affected. *Contact urticaria* describes lesions that occur at the site of direct contact with the food that may or may not also induce a reaction when ingested. Chronic urticaria is not commonly associated with food allergy.

The term *gastrointestinal anaphylaxis* describes isolated, acute gastrointestinal responses such as nausea, pain, vomiting and/or diarrhea induced by IgE-mediated mechanisms. Gastrointestinal anaphylaxis is uncommon, but gastrointestinal symptoms commonly accompany other organ system manifestations of acute, IgE antibody-mediated reactions to foods. A form of contact allergy that primarily affects the oropharynx is *pollen-food syndrome (oral allergy syndrome)*.¹³ Initial

KEY CONCEPTS

MANIFESTATIONS OF FOOD ALLERGY

A food allergy is likely when:

- >> Typical symptoms (e.g., urticaria, pruritus, symptoms of anaphylaxis) occur minutes following ingestion of a possible causal food.
- >> Certain chronic diseases are identified, such as moderate to severe atopic dermatitis in children, or eosinophilic gastroenteropathies.
- >> Patterns of illness are consistent with described syndromes of food allergy, such as vomiting and lethargy about 2 hours after the ingestion of an allergen in infants (enterocolitis), or mucous, bloody stools in a breastfed infant (proctocolitis).

sensitization to pollen proteins may result in symptoms when homologous proteins in particular fruits/vegetables are ingested. For example, the birch pollen protein Bet v 1 shares homology with apple Mal d 1. Additional relationships with birch pollen proteins include other Rosaceae family fruits, such as peach and plum. It is estimated that 50% of pollen-allergic persons may be affected. Symptoms are usually limited to the oropharynx with pruritus and mild angioedema, but progression to a systemic reaction may occur. Causal proteins are presumably heat-labile, as cooking the food typically abolishes the reaction. The disorder must be distinguished from mild oral reactions

CLINICAL PEARLS

FACTORS ASSOCIATED WITH SEVERE/FATAL REACTIONS

- >> Allergies to peanut, tree nuts, fish and shellfish (however other foods are potential causes)
- >> Delay in treatment with epinephrine
- >> Teenagers and young adults
- >> Asthma
- >> Lack of skin rash during a reaction
- >> Reactions to trace amounts
- >> Previous severe reactions

to stable proteins and oral reactions that may be a first symptom of a more progressive allergic response. The same foods that cause this oral syndrome may induce a systemic reaction in persons reactive to stable proteins they contain (e.g., lipid transfer proteins).

Chronic asthma and chronic allergic rhinitis are not typically attributable solely to food allergy. However, *respiratory symptoms* of rhinitis and wheezing may accompany systemic allergic reactions to ingested food allergens. Inhalation of airborne allergenic food proteins can also induce respiratory reactions, either in an occupational setting, e.g., baker's asthma from wheat, or when stable proteins become aerosolized during cooking or processing.

Food-induced anaphylaxis is a serious systemic allergic reaction that is rapid in onset and can cause death.¹⁴ Symptoms can vary and may affect any of a combination of organ systems among the skin, respiratory tract, gastrointestinal tract and cardiovascular system. Symptoms may also include uterine contractions and an aura of 'impending doom.' Although a variety of mild symptoms such as urticaria and abdominal pain can occur, life-threatening symptoms include laryngeal edema, severe asthma, and cardiovascular compromise (Chapter 42). Serum tryptase elevation is often not detected during food-associated anaphylaxis. There are currently no simple tests to determine an individual's risk of severe or fatal anaphylaxis, but epidemiological factors such as age and food may define a high-risk group. Reactions can be biphasic, with initial symptoms waning and severe symptoms recurring 1–2 hours or more later. If anaphylaxis only occurs when exercise follows ingestion of the causal food, the diagnosis is *food-associated, exercise-induced anaphylaxis*. The syndrome of exercise-related food anaphylaxis is most commonly reported after eating wheat or celery, but some individuals experience anaphylaxis with exercise after any meal.

MIXED IgE/NON-IgE-ASSOCIATED (ATOPIC DERMATITIS/EOSINOPHILIC GASTROINTESTINAL DISEASE)

Studies using double-blind, placebo-controlled oral food challenges show that approximately one in three young children with moderate to severe *atopic dermatitis* has a food allergy.¹⁵ Removal of triggering foods may improve the skin condition. Food-responsive atopic dermatitis can also

occur in adults, but appears much less common and has been less well studied. Most studies reveal that food-specific IgE antibody is detectable to the foods that cause symptoms. However, food-responsive disease has also been documented in children without detectable IgE to the causal food; therefore, cell-mediated mechanisms are also probably involved. Because of the chronic nature of the disorder, and its waxing and waning course, it is difficult to link symptoms with particular foods by history alone. More than 90% of reactions in children are attributed to milk, egg, wheat and soy. It is less common to verify a role for meats, fruits or vegetables.

Allergic eosinophilic esophagitis/gastroenteritis is a group of disorders characterized by eosinophilic inflammation in the gastrointestinal tract (Chapter 46). Symptoms overlap those of other gastrointestinal disorders and may include dysphagia, vomiting, diarrhea, obstruction, and malabsorption. Studies in children indicate that almost all patients are food responsive, although implicated foods may or may not be associated with evidence of IgE antibody.¹⁶

NON-IgE-ASSOCIATED DISORDERS

Similar to the IgE-associated disorders, these disorders may also affect various target organs.² *Contact dermatitis*, a type IV hypersensitivity response, can occur from contact with foods in occupational handling. Fixed, raised, erythematous eruptions, similar to fixed drug eruptions, have rarely been attributed to foods. *Dermatitis herpetiformis* is a papulovesicular skin rash associated with celiac disease caused by an immune response to gluten.

A rare pulmonary disorder affecting infants, *Heiner's syndrome or milk-induced pulmonary hemosiderosis*, is associated with precipitating (IgG) antibodies to cow's milk. Symptoms include anemia, pulmonary infiltrates, recurrent pneumonia, and growth failure, which resolve with milk elimination.

Several nonIgE-mediated disorders of the gastrointestinal tract have been identified in infants.¹² *Food protein-induced proctocolitis* is characterized by mucus and blood in stools. Patients are usually breastfed infants and the bleeding usually resolves with maternal exclusion of cow's milk. Rarely, foods other than milk are implicated. The infants generally appear well. Empiric dietary therapy is commonly instituted, but if rectal biopsy is performed, an eosinophilic inflammation is observed. The disorder is generally not associated with detectable IgE antibody to milk and resolves by age 1–2 years. Infants with *food protein-induced enteropathy* experience diarrhea, poor growth and edema due to hypoproteinemia caused by malabsorption. Biopsy reveals non-specific inflammation of the jejunum with increased lymphocytes, plasma cells and eosinophils, and partial villus blunting. Enteropathy syndromes attributed to cow's milk protein usually resolve in 1–2 years. In contrast, *celiac disease*, a specific type of enteropathy, is caused by immune reactions to gluten (e.g., wheat, rye, barley) and is often associated with the HLA-DQ2 haplotype (Chapter 74). The inflammatory response remits with dietary exclusion of gluten but, unlike cow's milk enteropathy the disorder does not resolve and so lifetime exclusion of gluten is needed. A dramatic form of nonIgE mediated gastrointestinal food allergy is *food protein-induced enterocolitis*. Primarily a disorder of infants, this is characterized by a symptom complex of profuse vomiting and heme-positive diarrhea, leading to failure to thrive, and potentially to dehydration and shock during chronic ingestion of the causal protein. These infants also may develop

acidemia and methemoglobinemia, and present with a sepsis-like picture including an elevated peripheral polymorphonuclear leukocyte count. Cow's milk and soy are most often responsible, but grains such as rice and oats, and poultry, are an increasingly recognized trigger. Ingestion of the causal protein may lead to a delayed (about 2 hours) recurrence of symptoms that may be severe and include shock. Resolution usually occurs in 2–3 years.

■ PATHOPHYSIOLOGY ■

IMMUNE MECHANISMS AND THE GASTROINTESTINAL BARRIER

The first line of gastrointestinal defense against microbes and allergens is the gastrointestinal surface, which poses both a physical and an immunologic barrier.⁴ The mucosal surface physical barrier includes luminal contents that present enzymes, extremes of pH, and bile salts that disrupt pathogens and allergens. The mucosal surface also presents a physical barrier because glycocalyx and a thick mucous layer overlie epithelial cells joined by tight junctions. Studies in mice, and observations in humans, indicate that neutralizing gastric pH can alter the gastrointestinal barrier in a way that may promote sensitization to ingested food antigens and increase the likelihood of reactions. One theory for the disposition of infants toward allergic responses to foods is the developmental immaturity of the gut barrier: for example, enzymatic activity is suboptimal in the newborn period. Nonetheless, about 2% of ingested food antigens are absorbed and transported throughout the body in an immunologically intact form in adults; therefore, additional immune mechanisms must be active to promote tolerance.

An active immune response involving both innate immunity (e.g., NK cells, polymorphonuclear leukocytes, macrophages, epithelial cells and Toll-like receptors) and adaptive immunity (e.g., intraepithelial and lamina propria lymphocytes, Peyer's patches, sIgA and cytokines), result in a moderated immune response to food proteins and oral tolerance.^{4, 17} The immunologic mechanisms involved in oral tolerance have not been fully elucidated. Central roles for antigen-presenting dendritic cells and regulatory T cells have been identified. Dendritic cells residing within the lamina propria and the noninflammatory environment of Peyer's patches produce IL-10 and IL-4, which favor the generation of tolerance. Regulatory T cells have been identified that modulate gastrointestinal inflammation and prevent adverse responses. These include Th3 cells, a population of CD4 cells that secrete TGF- β ; TR1 cells, CD4 cells that secrete IL-10; CD4, CD25⁺ regulatory T cells; CD8 suppressor T cells; and $\gamma\delta$ T cells. Intestinal epithelial cells may act as nonprofessional antigen-presenting cells because they present luminal antigens to T cells on an MHC class II complex, but lack a 'second signal.' The potential for allergens to transverse the gastrointestinal barrier in intact form (see below), the dose and the frequency of exposure can also influence tolerance. High dose tolerance involves deletion of effector T cells, whereas low dose tolerance is mediated by activation of regulatory T cells with suppressor functions. Commensal gut flora may also influence oral tolerance. Mice raised in a germ-free environment from birth fail to develop normal tolerance, and mice treated with antibiotics after birth are more easily sensitized to food protein.

Homing of food-responsive T cells to target organ sites of inflammation may account for organ specificity in food allergic disease. For

example, when stimulated *in vitro* with milk protein, peripheral blood mononuclear cells from children with milk-responsive atopic dermatitis express the skin homing receptor cutaneous lymphocyte antigen, whereas cells from patients with isolated gastrointestinal reactions to milk do not.¹⁸

FOOD ALLERGENS AND ADDITIVES

Certain food allergens are relatively stable to acid and heat and typically sensitize via the oral route (traditional, or class I food allergy),⁵ though they may also sensitize through ambient environmental exposures, for example in occupational asthma or skin contact with topical cosmetics. In contrast, class II food allergens are labile proteins and initial sensitization occurs primarily through respiratory exposure to homologous proteins in pollens. In accordance with the immunopathogenesis, class I food allergy typically occurs in infants or children during a presumed window of immunologic immaturity. In contrast, class II food allergy also affects adults (e.g., pollen-food related or oral allergy syndrome).

The major food allergens identified as class I allergens are water-soluble glycoproteins 10–70 kDa in size and fairly stable to heat, acid and proteases; examples include proteins in milk (caseins, β -lactoglobulin), peanut (vicillins, conglutin), egg (ovomucoid, ovalbumin), fish (parvalbumin), and nonspecific lipid transfer proteins found, for example, in apple (Mal d 3) or corn (Zea m 14). In contrast, class II allergens are generally labile, for example pathogen-related protein 10 in birch pollen (Bet v 1) that can induce sensitization through the respiratory route or can result in oral symptoms of pruritus to homologous proteins, such as in raw apple (Mal d 1) or carrot (Dau c 1). A limited number of related proteins make up the majority of food allergens (e.g., proteins in the cupin superfamily, the prolamin superfamily, and proteins in the plant defense system pathogenesis-related proteins).¹⁹ An individual may mount an immune response to various proteins in a specific food, and towards various segments (epitopes) of a particular protein – this pattern may correlate with expression of disease. For example, major class I allergens in peanut include Ara h 1, 2 and 3, which are associated with severe peanut allergy. On the other hand, Ara h 8 is a bet v 1 homolog, class II peanut allergen, which is less likely to be associated with severe clinical reactions. The specific number of proteins or epitopes recognized may also relate to clinical outcome. Broader patterns of IgE recognition, e.g., to many proteins and epitopes of a specific food, may be associated with a higher chance of a clinical allergic reaction. It has been suggested that IgE antibodies that recognize epitopes dependent on tertiary allergen structure are associated with transient childhood allergy, whereas IgE antibodies that recognize epitopes that are not dependent on complex protein folding (i.e., linear epitopes) are associated with persistent allergy.³ These and additional factors, such as heating a food and the matrix in which a food protein resides, can influence disease outcomes.

Whereas many botanically related proteins or animal proteins from similar species share regions of homology and may show cross-reactivity on allergy testing, clinical evidence of cross-reactivity is not as common.²⁰ Table 45.3 shows examples of common food allergens and describes important features and the implications for cross-reactivity. Virtually every food or derivatives (e.g., gelatin, colors or flavors) from meats, fruits, vegetables, grains, etc., has been described to cause a food allergic reaction, at least occasionally.¹⁰ The term 'spice' is

Table 45.3 Features of selected food allergens

Food	Selected allergenic proteins	Clinical issues and cross-reactions
Cow's milk	Bos d 4 α -lactalbumin Bos d 5 β -lactoglobulin Bos d 8 casein	Allergy to most mammalian milks (goat's, sheep's) is common (>90%)
Egg	Gal d 1 ovomucoid Gal d 2 ovalbumin	
Peanut	Ara h 1 vicilin Ara h 2 conglutin Ara h 3 glycinin Ara h 8 homologue to birch Bet v 1	Uncommon to be reactive to other legumes (<5%) such as soy, pea
Codfish	Gad c 1 parvalbumin	Common to be allergic to other finned fish (~75%), but allergy to specific species possible (presumed reaction to other fish proteins)
Shrimp	Pen a 1 tropomyosin	Common to be allergic to other crustacean shellfish (~75%), but allergy to specific species possible (presumed reaction to other shellfish proteins)
Wheat	Tri a 19 ω -5-gliadin	Uncommon to be reactive to other grains
Apple	Mal d 1 homologue to birch Bet v 1 Mal d 3 lipid transfer protein Profilin actin-binding protein	Homologous protein responsible for oral allergy syndrome

often used to describe a variety of flavoring agents, such as basil, cardamom, cinnamon, fennel, garlic, parsley, pepper, peppermint, rosemary, saffron, turmeric, and many others. These 'spices' represent a huge array of types of foods having proteins that share features with other foods and pollens. Therefore, this large group could be expected to include allergens accounting for allergic reactions in a subset of patients.

A variety of substances may be added to foods to enhance flavor, preservation, color, or texture. Certain food additives are derived from natural sources and contain proteins that have been associated with allergic reactions, e.g., colors derived from turmeric, paprika, beet, seeds (annatto) and insects (carmine/cochineal).¹¹

Chemical additives are not likely to cause IgE-associated allergic reactions, but some may have drug effects that cause adverse reactions, including symptoms that are allergy-like, or which may invoke an immune response. Tartrazine (Yellow #5) is a synthetic color that has been extensively investigated because of concerns that it may trigger hives, allergic reactions and asthma. However, well-conducted studies have generally not validated these concerns. Like tartrazine, many other synthetic colors (sunset yellow, erythrosine, ponceau 4R, carmoisine, quinoline yellow, patent blue and others) have not been proved to cause allergic reactions, but some have rarely been associated with illnesses such as rashes. Sulfites are added to foods as a preservative, an anti-browning agent, or for a bleaching effect. In sensitive persons, sulfites can induce asthma, and very rarely cause more significant allergy-like

KEY CONCEPTS

PATHOPHYSIOLOGIC EXPLANATIONS FOR CLINICAL MANIFESTATIONS

- >> Heat- and digestion-resistant proteins are more likely to cause anaphylaxis/systemic reactions.
- >> Labile food proteins are less likely to cause systemic reactions, and heating may abrogate reactions.
- >> Homing of food-reactive T cells to target organs may account for particular disease manifestations, e.g., atopic dermatitis compared to isolated gastrointestinal disease.
- >> Expression of IgE that binds to sequential amino acids, compared to those that bind to epitopes that depend on tertiary conformational structures, are associated with a persistent allergy.
- >> The matrix in which a protein resides, and the effect of heating, may alter its presentation to the immune system, either reducing or enhancing reactions.

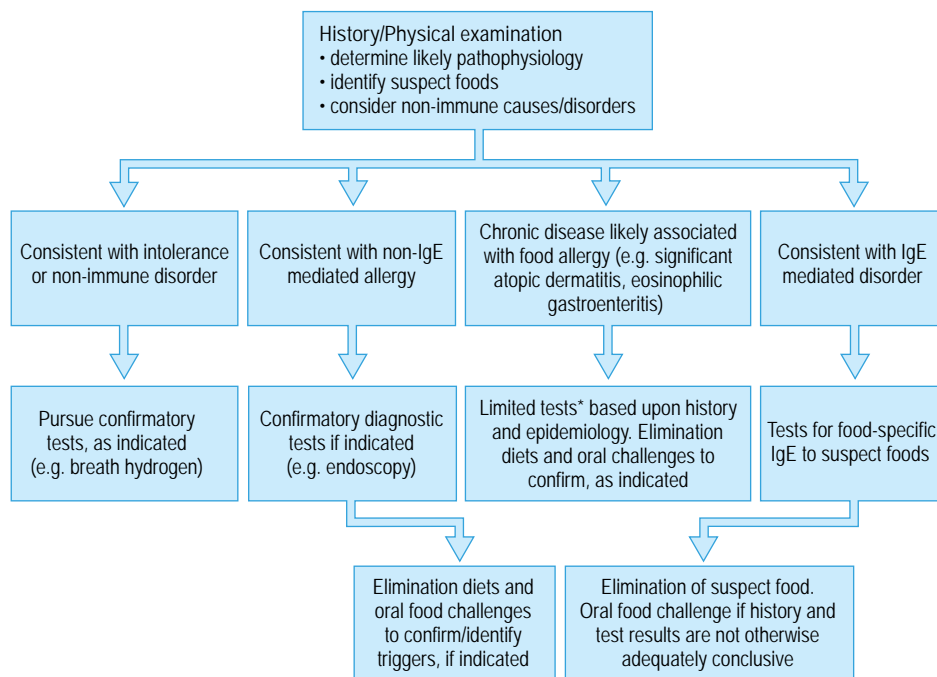

Fig. 45.1 General diagnostic scheme. The history is the key starting point toward diagnosing a food allergy, or alternative explanation for an adverse event to foods. This illustration provides a conceptual framework only, see text for additional explanations. * Certain test results may be intrinsically 'diagnostic' (see text).

responses. Sulfites are used to preserve some drugs, including epinephrine, but the low amounts used for epinephrine have never been reported to cause a reaction.

■ DIAGNOSIS ■

The clinical evaluation of an adverse reaction to food depends on a careful history and physical examination to determine the type of adverse response (as outlined in Table 45.1) and which food(s) might be responsible.⁵ Important factors to consider include the types of symptoms, their chronicity, reproducibility, and possible alternative explanations. If symptoms indicate that a nonimmune response is likely, additional evaluation would follow the specific suspicion. For example, lactose intolerance can be confirmed by hydrogen breath testing. If a food allergy is likely, the pattern of illness and list of possible triggers may disclose whether an IgE- or a non-IgE-associated disorder is likely, and will establish the type of testing that might be appropriate. Figure 45.1 shows a general diagnostic scheme. For chronic disorders such as atopic dermatitis and eosinophilic gastroenteritis, the identification of suspect foods is difficult because food is ingested throughout the day and symptoms are often chronic, with a waxing and waning course. Symptom diaries are helpful, but rarely diagnostic. In addition, individuals with these disorders often test positive to multiple foods that may not be causing illness. Care in selecting and interpreting the tests is paramount.

To determine food-specific IgE antibodies, skin-prick tests (SPTs) performed using a probe to introduce food protein to the superficial skin

CLINICAL PEARLS

CLUES AND PITFALLS IN DIAGNOSTIC TESTING

- >> The history is paramount to provide prior probability assessments to select and interpret tests.
- >> In the event of a convincing reaction, a negative test should not be relied on to exclude allergy; additional testing and physician-supervised oral food challenges may be needed.
- >> It is more likely that a food that is not commonly eaten is the cause of a reaction, compared to a new allergy to a routinely tolerated food.
- >> Testing of large 'panels' of foods without regard to patient history or the epidemiology of allergic diseases is often misleading because sensitization (positive tests for IgE) may occur without clinical consequences.
- >> The degree of positive testing may correlate positively with risk of reactions, but the exact nature of the relationship for most foods/clinical circumstances has not been determined.

layer, or serum tests, are generally sensitive (~75–95%) and specific (~30–60%).² SPTs are used on rash-free skin while the patient is avoiding antihistamines; intradermal skin tests should not be used. Although commercial extracts are available for performing skin-prick tests for many foods, fresh extracts may be more sensitive, particularly when testing fruits and vegetables whose proteins are prone to degradation. If IgE antibody specific for the food protein is present, a wheal and flare will occur that is compared to positive (histamine) and negative (saline–glycerine) controls. SPTs are considered positive if there is a mean wheal diameter of 3 mm or more, after subtraction of the saline control. Food-specific IgE antibodies can also be detected in serum (Chapter 100).

A positive SPT or serum IgE test merely indicates that food-specific IgE is present: it does not itself confirm an allergy. Increasingly larger wheal diameters or increasing concentrations of IgE antibodies are associated with an increasingly higher chance that the test reflects a clinical reaction. In a limited number of studies of a few foods in infants and/or children, diagnostic values associated with very high (>95%) predictive values for reactions have been determined, though not universally confirmed. A study using SPTs in young children revealed that when wheals were particularly large (> 8 mm for milk and peanut, and > 7 mm for egg) a clinical reaction was virtually certain.²¹ Studies determining the concentration of specific IgE antibody measured using a particular method (CAP-RAST FEIA or UniCap reported in arbitrary units, kU_A/L) showed that a food-specific IgE concentration of >7 kU_A/L to egg, >15 to milk, and >14 to peanut was 95% predictive for a reaction among 5-year-old children.²² For children under the age of 2 the values where most reacted were lower (e.g., > 2 kU_A/L for egg or milk). These results have not been widely confirmed.^{3,5} It must be emphasized that diagnostic concentrations have not been determined for other foods, allergic disorders or age groups.

Food-specific IgE may be detected despite tolerance of a food, or may remain detectable but typically decline as a food allergy resolves. Obtaining 'panels' of food allergy tests without considering the history is not good practice because numerous irrelevant positive results can occur. The history is crucial, because tests are expected to be negative when the pathophysiology of the response is consistent with a nonIgE-mediated reaction. However, acute anaphylactic reactions may also occur despite a negative test, so caution is needed when evaluating a patient with a convincing history despite a negative test. Neither the size of the SPT nor the level of IgE in serum usefully predicts the type or severity of reaction. Additional diagnostic tests are being researched. The atopy patch test (APT), which is performed by placing the food allergen on the skin under occlusion for 48 hours and assessing for a delayed rash at 24–72 hours, shows promise for nonIgE-mediated disorders, but more studies are needed to determine their utility.⁵ A host of tests have been touted for the diagnosis of food allergy, but have never been found useful in blinded studies. These include measurement of IgG₄ antibody, provocation–neutralization (drops placed under the tongue or injected to diagnose and treat various symptoms), and applied kinesiology (muscle strength testing).⁵

For evaluation of chronic disease, the amelioration of symptoms during dietary elimination of suspected foods provides presumptive evidence of causality. Elimination diets can be undertaken by removing foods suspected to be causing symptoms, removing all but a defined group of foods that are rarely allergenic (oligoantigenic diet), or by giving an elemental diet of only a hypoallergenic extensively hydrolyzed formula or a nonallergenic amino acid-based formula. The elemental diet provides the most

definitive trial. The type of elimination diet selected depends upon the clinical scenario, a priori reasoning concerning offending foods, and the results of tests for IgE antibody. The duration of the trial depends on the type of symptoms, but 1–6 weeks is usually the required range. A dietician may be needed to ensure nutritional sufficiency of trial diets. For breastfed infants, maternal dietary elimination is required. When a food to which IgE has been demonstrated is removed from the diet during a chronic disorder, it is possible for reintroduction to induce severe reactions.

When history and simple tests have not confirmed an allergy, or when tolerance is suspected, an oral food challenge (OFC) may be needed to confirm clinical allergy.⁵ An oral food challenge is performed by feeding gradually increasing amounts of the suspected food over hours or days. This requires physician observation and is performed either openly or blinded by camouflaging the food in a carrier food or opaque capsules. The double-blind, placebo-controlled oral food challenge is the method least prone to bias and is considered the 'gold standard' to diagnose food allergy. The OFC can be used to evaluate any type of suspected adverse response to foods. The procedure is most often needed when several foods are under consideration, tests for specific IgE are positive, and elimination resulted in resolution of symptoms. The challenge setting also provides a safe means to introduce foods that were highly suspected to cause severe reactions but showed negative skin or IgE tests. For nonIgE-mediated reactions, OFC is usually the only means of diagnosis. These feeding tests, particularly in IgE-mediated reactions and enterocolitis syndrome, can induce severe reactions. The supervising clinician must have medications and supplies for resuscitation immediately available to manage reactions. Challenges may be optional or contraindicated in certain circumstances, and the risks of the challenge must be weighed against the social and nutritional deficits of continued avoidance. Recent, severe anaphylaxis to an isolated ingestion, with a positive test for specific IgE antibody to the causal food, is one example of a relative contraindication because this scenario represents confirmation of a convincing history. Negative challenges should always be followed by a supervised open feeding of a relevant portion of the tested food in its commonly prepared state.

TREATMENT

Various modalities to induce tolerance or reduce reaction severity, such as oral immunotherapy, injection immunotherapy using modified proteins, monoclonal antibodies to block immune responses and other strategies, are under investigation.²³ However, the mainstay of treatment is avoidance of the food and preparation for treatment in the event of an accidental ingestion leading to an allergic reaction, including anaphylaxis. Dietary management of food allergy is fraught with nutritional and other pitfalls. In most countries, manufacturing and labeling deficiencies make it very difficult to identify allergens in commercial food products. Cross-contamination and errors in packaged food and restaurants are an additional obstacle. For children, dietary management in schools can be difficult due to food sharing, school projects using foods, parties, lack of on-site medical personnel, etc.

In the event of an allergic reaction, antihistamines may be required to reduce itching/rash. However, for patients experiencing more severe symptoms of anaphylaxis, with respiratory and/or cardiovascular symptoms, additional therapies are required (Chapter 42). Self-injectable epinephrine should be prescribed for those at risk of anaphylaxis.¹⁴ Guidelines for determining those who should have access to this

THERAPEUTIC PRINCIPLES

AVOIDANCE AND EMERGENCY CARE

Avoidance:

- >> Careful reading of food ingredient labels, meal preparation to avoid cross-contact
- >> Review approaches to restaurants (careful communication of allergy, avoiding higher risk cuisines based upon the allergen, caution about cross-contact in meal preparation)
- >> Seek dietician support to ensure adequate nutrition when numerous restrictions are in place

Treatment:

- >> Prescribe and train use of intramuscular epinephrine for self-injection
- >> Medical alert bracelets
- >> Alert emergency services for prompt advanced evaluation and emergency care of anaphylaxis
- >> Remain under medical observation 4 or more hours following a significant reaction (biphasic reaction could occur)
- >> Written/reviewed anaphylaxis action plans for schools/camps

medication are under scrutiny, but candidates include food-allergic patients with previous severe reactions, allergy to foods commonly causing severe reactions, and food-allergic patients with underlying asthma. It is essential to periodically review the indications and technique of administration of self-injectable epinephrine because mistakes are common. Patients must be instructed that following the administration of the medication they need prompt transportation to an emergency facility (by ambulance) with prolonged observation (> 4 hours), as recurrence of severe symptoms is possible. Patients should obtain medical emergency bracelets identifying their allergy, and be reminded to update expired and expended epinephrine injectors. For children, an important component of the school management of food allergy is to have a clear emergency plan in place, medications readily available, and school personnel trained in recognizing and treating reactions.

NATURAL HISTORY AND PREVENTION

Most (~85%) children lose their sensitivity to most allergenic foods (egg, milk, wheat, soy) within the first 3–5 years of life.²⁴ In contrast, adults with food allergy may have long-lived sensitivity. Sensitivity to peanut, tree nuts, and seafood is rarely lost. The notion that peanut and tree nut allergy is permanent derives partly from the observation that it is an allergy that affects adults; however, it has become apparent that about 20% of peanut-allergic children under age 2 years, and about 9% of those with tree nut allergy, may achieve tolerance by school age.

Evidence-based approaches to delay or prevent allergy through dietary manipulation of infants and mothers have been hampered by

KEY CONCEPTS

NATURAL COURSE

- >> Most (85%) childhood food allergies to milk, egg, wheat, soy resolve by age 5.
- >> Peanut, tree nut, fish and shellfish allergies are typically persistent.
- >> 20% of young children with a food allergy to peanut become tolerant by age 5.
- >> About 9% of young children with a tree nut allergy achieves tolerance.
- >> Allergy to peanut can 'recur'; a risk appears to be prolonged avoidance after apparent tolerance.
- >> For IgE-mediated reactions, test results may decline as tolerance develops.
- >> Most infant gastrointestinal allergies resolve by early childhood, but eosinophilic gastroenteropathies appear to be more persistent.

study design, because randomized controlled dietary trials are not possible. Studies suggest a beneficial role for exclusive breastfeeding of infants at 'high risk' for atopic disease for the first 3–6 months of life, and for avoiding supplementation with cow's milk or soy formulas in favor of hypoallergenic formulas if breastfeeding is not possible.²⁵ At present there are no conclusive studies indicating that the manipulation of the mother's diet during pregnancy or while breastfeeding, or the restriction of allergenic foods from the infant's diet, will prevent the development of food allergy, though such approaches have been suggested.

Eosinophil-associated gastrointestinal disorders (EGID)

Li Zuo, Marc E. Rothenberg

46

Accumulation of eosinophils in the gastrointestinal tract is a common feature of numerous gastrointestinal disorders, including classic IgE-mediated food allergy, eosinophilic gastroenteritis, allergic colitis, eosinophilic esophagitis (EE),^{1, 2} inflammatory bowel disease (IBD), and gastroesophageal reflux disease (GERD).^{3, 4} In IBD, eosinophils are only a small percentage of the infiltrating leukocytes, but their level has been proposed to be a negative prognostic indicator. In primary eosinophilic gastrointestinal disorders (EGID), which include EE, eosinophilic gastritis, eosinophilic enteritis, eosinophilic colitis and eosinophilic gastroenteritis, the gastrointestinal tract is affected by eosinophil-rich inflammation in the absence of known causes for eosinophilia (e.g., drug reactions, parasitic infections, malignancy, etc). Patients with EGID suffer various symptoms, including failure to thrive, abdominal pain, irritability, gastric dysmotility, vomiting, diarrhea, and dysphagia. EGID appear to arise from the interplay of genetic and environmental factors. Notably, ~10% of patients suffering from EGID have an immediate family member with EGID. Several lines of evidence support an allergic etiology: ~75% of patients with EGID are atopic; some patients improve on allergen-free diets; and mast cell degranulation is seen in tissue specimens. Animal models of EGID also support a potential allergic etiology.² Interestingly, despite the common finding of food-specific IgE in EGID patients, food-induced anaphylactic responses occur in only a minority of patients. Thus, EGID fall between pure IgE-mediated food allergy and cellular-mediated hypersensitivity disorders (such as celiac disease) (Fig. 46.1).

Although the incidence of primary EGID has not been rigorously calculated, a mini-epidemic of these diseases (especially EE) has been noted over the last decade.¹ For example, EE has been reported in Australia,⁵ Brazil,⁶ England, Italy, Japan,⁷ Spain, and Switzerland.⁸ In a specialty clinic ~10% of pediatric patients with GERD-like symptoms who were unresponsive to acid blockade had EE.⁹ Others have reported that 6% of children with esophagitis have EE.¹ Prevalence estimates vary from 1:70 000 adults in Australia to 1:2000 children in Cincinnati, USA. Collectively, these data indicate that EGID are not uncommon, and may be even more prevalent than pediatric IBD.

EGID typically occur independent of peripheral blood eosinophilia (>50% of the time), indicating the potential significance of

gastrointestinal-specific mechanisms for regulating eosinophil levels. However, some patients with EGID (typically those with eosinophilic gastritis) have substantial peripheral blood eosinophilia and meet the diagnostic criteria for the idiopathic hypereosinophilic syndrome (HES). HES is defined by sustained peripheral blood eosinophilia (>1500 cells/mm²) and end-organ involvement, in the absence of known causes for eosinophilia.^{10, 11} Notably, whereas HES commonly involves the gastrointestinal tract, the other organs typically affected in HES (heart and skin) are rarely involved in EGID. Some patients with HES have a microdeletion on chromosome 4 that generates an activated tyrosine kinase susceptible to imatinib mesylate therapy; the possible occurrence of this and other genetic events in EGID patients, especially those with significant peripheral eosinophilia, is currently being investigated.

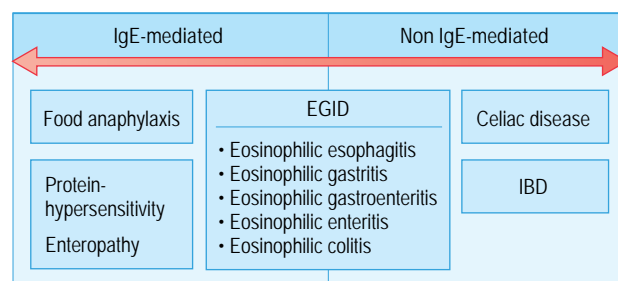

Fig. 46.1 The spectrum of gastrointestinal inflammatory disorders involving eosinophils. Gastrointestinal eosinophils accumulate in a variety of disorders with variable dependence upon IgE, ranging from predominant IgE dependence (food anaphylaxis) to nonIgE dependence (celiac disease). Primary eosinophilic gastrointestinal disorders (EGID) are in the middle of the spectrum and have some overlap with pure protein hypersensitivity disorders and inflammatory bowel disease (IBD). (Adapted From Rothenberg ME, Mishra A, Brandt EB, Hogan SP. Gastrointestinal eosinophils in health and disease. *Adv Immunol* 2001; 78: 291–328, with permission from American Academy of Allergy, Asthma and Immunology.)

KEY CONCEPTS

ASSOCIATIONS BETWEEN IgE-MEDIATED AND DELAYED TH2-TYPE RESPONSES IN EOSINOPHIL ASSOCIATED GASTROINTESTINAL DISORDERS

- >> EGID primarily affects the gastrointestinal tract with eosinophil-rich inflammation in the absence of known causes of eosinophilia.
- >> There is a strong family history of EGID in approximately 10% of patients.
- >> EGID is associated with atopy especially food allergy.
- >> EGID is independent of peripheral blood eosinophilia in >50% of patients.

■ CONSTITUTIVE GASTROINTESTINAL EOSINOPHILS ■

Eosinophils are present at low levels in many tissues. In a large series of biopsy and autopsy specimens, the only organs with substantial tissue eosinophilia were the gastrointestinal tract, spleen, lymph nodes, and thymus. Interestingly, eosinophil degranulation was only seen in the gastrointestinal tract. In healthy mice, eosinophils are normally present in the lamina propria of the stomach, small intestine, cecum, and colon. Eosinophils are not normally present in Peyer's patches or intraepithelial locations, although they commonly infiltrate these regions in EGID.² Interestingly, prenatal mice have eosinophils located in similar regions and concentrations as observed in adult mice, indicating that eosinophil homing into the gastrointestinal tract occurs independent of gut flora. Germ-free mice and mice deficient in innate signaling responses (Myd88 deficient) have normal numbers of gastrointestinal eosinophils. These data suggest that eosinophils respond to distinct stimuli compared to other intestinal leukocytes; indeed, constitutive expression of eotaxin-1 is the unique signal that promotes localization of eosinophils into the gastrointestinal tract. Tissue-dwelling eosinophils have distinct cytokine expression patterns under inflammatory or noninflammatory conditions, with esophageal eosinophils from EE patients expressing relatively high levels of Th2 cytokines.¹²

■ PROINFLAMMATORY ROLE OF EOSINOPHILS IN EGID ■

In vitro, the granule constituents of eosinophils are toxic to many tissues, including intestinal epithelium. The eosinophil cationic proteins major basic protein (MBP), eosinophil peroxidase (EPO), and eosinophil cationic protein (ECP) are cytotoxic to epithelium at concentrations similar to those found in biological fluids from patients with eosinophilia. ECP can render cell membranes porous, facilitating the entry of other toxic molecules. MBP increases smooth muscle reactivity by affecting vagal muscarinic M2 receptors and triggers mast cell and basophil degranulation. Eosinophils can generate a wide range of inflammatory cytokines, indicating that they could modulate multiple aspects of the immune response

Table 46.1 Diagnostic work-up for EGID (Adapted from Rothenberg ME, Mishra A, Brandt EB, Hogan SP. Gastrointestinal eosinophils in health and disease. *Adv Immunol* 2001; 78: 291–328, with permission from Elsevier)

involving epithelial growth, fibrosis, and tissue remodeling. Other toxic products include hydrogen peroxide, halide acids, and the leukotrienes LTC₄, LTD₄ and LTE₄, which increase vascular permeability and mucus secretion and stimulate smooth muscle contraction. In patients with eosinophilic gastroenteritis, MBP and ECP are deposited extracellularly in the small bowel, and ultrastructural changes in eosinophil secondary granules (indicating degranulation and mediator release) are found in duodenal biopsies. Furthermore, Charcot–Leyden crystals are commonly found in feces, and disease severity correlates with mucosal eosinophil numbers.

■ CLINICAL EVALUATION OF EGID ■

Patients with EGID present with a variety of clinical problems, most commonly failure to thrive, abdominal pain, irritability, gastric dysmotility, vomiting, diarrhea, dysphagia, microcytic anemia, and hypoproteinemia. All patients with these refractory problems, especially individuals with a strong history of allergic diseases, peripheral blood eosinophilia, and/or a family history of EGID (Table 46.1), should be evaluated for EGID. Depending on the intestinal segment involved, the frequency of specific symptoms varies (e.g. abdominal pain and dysphagia are most common in eosinophilic gastroenteritis and EE, respectively), but there are no pathognomonic symptoms or blood tests for diagnosing EGID. Notably, blood eosinophil counts are not substantially elevated in the majority of patients. If EGID is suspected (based on clinical presentation or evaluation of endoscopic biopsies), then additional testing should be considered to exclude other primary disease processes, such as drug hypersensitivity, collagen-vascular disease, malignancy, or infection (Table 46.1).

Evaluation for EGID starts with a comprehensive history and physical examination. Evaluation for intestinal parasites by examination of stool samples, intestinal aspirates obtained during colonoscopy, or specific blood antibody titers should be performed, especially when patients have high-risk exposure (e.g., living on a farm, or drinking well water). In one series

CLINICAL PEARLS

EOSINOPHIL-ASSOCIATED GASTROINTESTINAL DISORDERS (EGID)

- >> Most common symptoms: Failure to thrive, abdominal pain, irritability, gastric dysmotility, vomiting, diarrhea, dysphagia, and food impaction.
- >> A diagnostic evaluation should be performed in all patients with these refractory problems, especially in individuals with a strong history of allergic diseases, peripheral blood eosinophilia, and/or a family history of EGID.
- >> Rule out other possibilities with additional testing for another primary disease process, such as drug hypersensitivity, collagen-vascular disease, malignancy, or infection.
- >> The diagnosis of EGID is dependent on the microscopic evaluation of endoscopic biopsy samples, with careful attention to the quantity, location, and characteristics of the eosinophilic inflammation. Patients with EGID often present with a clear history and positive biopsy results for the disease but have a variety of endoscopic findings, including a normal endoscopic appearance.

of patients with eosinophilic enteritis, the common dog hookworm *Ancylostoma caninum* was identified as the cause in 15% of cases. Infection with *Strongyloides stercoralis* should be excluded before using immunosuppressant agents in EGID patients, because this infection can become life-threatening with systemic immunosuppression. Total IgE levels may help stratify patients with atopic variants of EGID or suggest further consideration for occult parasitic infections. Allergy to foods is common in patients with the atopic variant of EGID and can be demonstrated by skin-prick testing. Delayed cutaneous hypersensitivity testing (skin patch testing) for food antigens can help identify further allergic variants of EE.¹³

The diagnosis of EGID is dependent on the microscopic evaluation of endoscopic biopsy samples, with careful attention to the quantity, location, and characteristics of the eosinophilic inflammation. Patients with EGID often present with a clear history and positive biopsy results for the disease but have a variety of endoscopic findings.⁸ It is not uncommon for the gastrointestinal tract to look normal endoscopically; because of this, microscopic evaluation of biopsy samples is essential. Moreover, the disease often has patchy involvement, necessitating analysis of multiple endoscopic biopsies from each intestinal segment. Because no widely accepted diagnostic criteria have been established for EGID, the diagnosis is dependent on the expertise of the pathologists evaluating the biopsies. Whereas the normal esophagus is devoid of eosinophils, the rest of the gastrointestinal tract contains readily detectable eosinophils. Thus, differentiation of EGID from the normal state relies on several factors, including (1) eosinophil quantification (and comparisons to normal values at each medical center); (2) the location of eosinophils (e.g., their presence in abnormal positions such as the intraepithelial and intestinal crypt regions); (3) associated pathological abnormalities (e.g., epithelial hyperplasia, as in the case of EE); and (4) the absence of pathological features suggestive of other primary disorders. Owing to difficulties of interpretation, EGID patients often have symptoms for a long time (mean 4 years) before a definitive diagnosis is established.

EVALUATION FOR HES IN PATIENTS WITH APPARENT EGID

The term hypereosinophilic syndrome (HES) describes patients with systemic symptoms due to marked eosinophilia. Diagnostic criteria for HES include persistent eosinophilia of at least 1500 cells/mm² for >6 months; lack of known causes for eosinophilia; and symptoms and signs of organ system involvement. Patients with EGID and blood eosinophil counts >1500/mm² meet these diagnostic criteria, but they generally do not have the high risk of life-threatening complications associated with classic HES (i.e., the cardiomyopathy or central nervous system involvement).

A major advance in our understanding of HES has followed treatment of HES patients with the tyrosine kinase inhibitor imatinib mesylate, which was introduced for the treatment of chronic myelogenous leukemia. In many HES patients, treatment with imatinib mesylate dramatically reduces peripheral blood and bone marrow eosinophils, suggesting that certain HES patients express a novel kinase sensitive to imatinib mesylate. Further investigation has revealed the existence of an 800 kilobase deletion in chromosome 4 bringing together an upstream DNA sequence homologous to a yeast protein (FIP1), and the gene for the cytoplasmic domain of the platelet-derived growth factor- α (PDGFRA) receptor. This fusion gene is transcribed and translated, yielding a novel kinase (FIP1-L1-PDGFRA); FIP1-L1-PDGFRA is exquisitely sensitive to imatinib *in vitro*, explaining the remarkable sensitivity of HES patients to imatinib. Patients responsive to imatinib are those with most 'classic' HES, i.e., males aged 20–50 who present with marked peripheral eosinophilia. Recently, these patients have been shown to meet minor criteria for systemic mastocytosis, having elevated levels of serum mast cell tryptase and high numbers of dysplastic mast cells in the bone marrow. They are prone to develop eosinophilic endomyocardial disease with embolization, but it appears that any disease that results in prolonged and marked eosinophilia can be associated with endomyocardial disease. Accordingly, routine surveillance (e.g., echocardiograms and plethysmography) is warranted in patients with EGID and peripheral blood eosinophilia. Conversely, the diagnosis of HES should always be considered in patients with EGID, especially those who develop extra-gastrointestinal manifestations. Additional diagnostic testing for HES may include bone marrow analysis (searching for myelodysplasia), serum tryptase and vitamin B₁₂ levels (both moderately elevated in classic HES), and genetic analysis for the FIP1L1-PDGFRA fusion event (Table 46.1).

EOSINOPHILIC ESOPHAGITIS

The esophagus is normally devoid of eosinophils.^{1,2} Disorders associated with esophageal eosinophil infiltration include EE, eosinophilic gastroenteritis, GERD, recurrent vomiting, parasitic and fungal infections, IBD, HES, esophageal leiomyomatosis, myeloproliferative disorders, carcinomatosis, periarteritis, allergic vasculitis, scleroderma and drug injury.^{4,14} Eosinophil-associated esophageal disorders are classified into primary and secondary. The primary subtype includes the atopic, nonatopic and familial variants, and the secondary subtype is subdivided into those with and without systemic eosinophilia (Table 46.2). EE is familial in about 10% of patients.

CLINICAL PEARLS

EOSINOPHILIC ESOPHAGITIS (EE)

- >> The majority of EE patients have evidence of food and aeroallergen hypersensitivity as defined by skin-prick and/or RAST testing.
- >> The esophagus is normally devoid of eosinophils, so the finding of esophageal eosinophils denotes pathology. By endoscopic biopsy, up to 7 eosinophils/hpf (400×) is most indicative of GERD; 7 to 20–24 eosinophils/hpf probably represents a combination of GERD and EE; and more than 20–24 eosinophils/hpf is characteristic of EE.
- >> The presence of GERD does not exclude the diagnosis of EE or food allergy, demonstrating the importance of a food allergy evaluation in these patients.
- >> A trial of specific food antigen and aeroallergen avoidance is often indicated for patients with atopic EE, and if unsatisfactory or practically difficult (when patients are sensitized to many allergens), a diet consisting of an elemental formula is advocated.
- >> Systemic steroids are used for acute exacerbations, while topical are used to provide long-term control. When using topical steroids we recommend the use of a metered-dose inhaler without a spacer. The patient is instructed to swallow the dose to promote deposition on the esophageal mucosa.
- >> Even if GERD is not present, neutralization of gastric acidity (with proton pump inhibitors) may improve symptoms and the degree of esophageal pathology.

ETIOLOGY OF EE

The etiology of EE is poorly understood, but food allergy has been implicated. Most EE patients have evidence of specific IgE to foods and aeroallergens, but only a minority have experienced food anaphylaxis.¹ Esophageal eosinophilia may be linked to pulmonary inflammation, as repeated delivery of allergens or IL-13 to the lungs of mice induces experimental EE. In humans, patients with seasonal allergic rhinitis have increased esophageal eosinophil accumulation,¹⁵ and patients with EE commonly report seasonal variations in symptoms. In addition to eosinophils, T cells and mast cells are elevated in esophageal mucosal biopsies, suggesting a chronic Th2-associated inflammation.¹⁶ Consistent with this, over-expression of IL-5 induces EE, and neutralization of IL-5 completely blocks allergen- or IL-13-induced EE in mice.¹⁷

In a recent genome-wide microarray profile analysis of esophageal tissue¹⁸ from patients with either EE or chronic esophagitis (typical of GERD) and normal controls, an EE genetic signature was found with dysregulated expression of ~1% of the entire human genome. Interestingly, eotaxin-3 was the most over-expressed gene in EE patients, and levels correlated with disease severity. Furthermore, a single nucleotide polymorphism (SNP) in eotaxin-3 was over-represented in EE patients. Conversely, mice lacking the eotaxin receptor (CCR3) were protected from developing experimental EE. Notably, eotaxin-3 is induced by IL-13. Taken together, these results strongly implicate eotaxin-3 in the

Table 46.2 Classification of eosinophil-associated gastrointestinal disorders (Adapted from Rothenberg ME. *J Allergy Clin Immunol* 2004; 113: 11–28, with permission from Elsevier).

Eosinophil-associated esophagitis

- Primary
 - Atopic
 - Nonatopic
 - Familial
- Secondary
 - Eosinophilic disorders
 - Eosinophilic gastroenteritis
 - Hypereosinophilic syndrome
 - Noneosinophilic disorders
 - Iatrogenic
 - Infection
 - Gastroesophageal reflux disease
 - Esophageal leiomyomatosis
 - Connective tissue disease (scleroderma)

Eosinophil-associated gastroenteritis

- Primary (mucosal, muscularis, and serosal forms)
 - Atopic
 - Nonatopic
 - Familial
- Secondary
 - Eosinophilic disorders
 - Hypereosinophilic syndrome
 - Noneosinophilic disorders
 - Celiac disease
 - Connective tissue disease (scleroderma)
 - Iatrogenic
 - Infection
 - Inflammatory bowel disease
 - Vasculitis (Churg–Strauss syndrome)

Eosinophil-associated colitis

- Primary eosinophilic colitis (also allergic colitis of infancy)
 - Atopic
 - Nonatopic
- Secondary
 - Eosinophilic disorders
 - Eosinophilic gastroenteritis
 - Hypereosinophilic syndrome
 - Noneosinophilic disorders
 - Celiac disease
 - Connective tissue disease (scleroderma)
 - Iatrogenic
 - Infection
 - Inflammatory bowel disease

Table 46.3 Comparison of EE and GERD (Adapted from Rothenberg ME, Mishra A, Brandt EB, Hogan SP. Gastrointestinal eosinophils in health and disease. *Adv Immunol* 2001; 78: 291–328, with permission from Elsevier)

Characteristic features	EE	GERD
Clinical		
Prevalence of atopy	Very high	Normal
Prevalence of food sensitization	Very high	Normal
Gender preference	Male	None
Abdominal pain and vomiting	Common	Common
Food impaction	Common	Uncommon
Investigative findings		
pH probe	Normal	Abnormal
Endoscopic furrowing	Very common	Occasional
Histopathology/pathogenesis		
Involvement of proximal esophagus	Yes	No
Involvement of distal esophagus	Yes	Yes
Epithelial hyperplasia	Severely increased	Increased
Eosinophil levels in mucosa	>24/hpf	0–7/hpf
Elevated eotaxin-3 level	Yes	No
Treatment		
H ₂ -blockers	Not helpful	Helpful
Proton pump inhibitors	Sometimes helpful	Helpful
Glucocorticoids	Helpful	Not helpful
Specific food antigen elimination	Sometimes helpful	Not helpful
Elemental diet	Helpful	Not helpful

pathoetiology of EE. Further work is needed to understand the molecular basis of the specific dysregulation of eotaxin-3 (and not other eotaxin chemokines).

CLINICAL AND DIAGNOSTIC STUDIES FOR EE

Patients with primary EE may report vomiting, epigastric or chest pain, dysphagia, and respiratory obstructive problems.¹⁹ In a recent study of 26 adult patients, all had dysphagia and 11 had food impaction; 19 of those 26 patients responded well to EE treatment.²⁰ Patients are predominantly male¹⁹ and have relatively intense esophageal eosinophilia,² extensive epithelial hyperplasia, and are frequently atopic compared to GERD patients (Table 46.3). The number and location of eosinophils is helpful when trying to differentiate EE from GERD. Up to 7 eosinophils/hpf (high-power field; 400×) is more indicative of GERD; 7 to 20–24 eosinophils/hpf probably represents a continuum of GERD and EE; >20–24 eosinophils/hpf suggests EE.² The presence of eosinophils in the proximal and distal esophagus

denotes EE, whereas eosinophil accumulation mainly in the distal esophagus suggests GERD.¹ In EE the esophageal mucosa is thickened, with basal layer hyperplasia and papillary lengthening. EE is associated with esophageal dysmotility; the etiology of the motor disturbances is unclear, but may be due to eosinophil activation and degranulation. Esophageal ultrasound shows dysfunctional muscularis mucosa in EE patients,²¹ and radiographic and endoscopic studies have shown strictures, mucosal rings, furrowing, ulcerations, whitish papules and polyps.²² Clinical assessment of EE includes analysis of food and aeroallergen sensitization and exclusion of GERD as well as other causes of eosinophils in the esophagus. Evaluation of food protein sensitization by delayed skin patch testing may increase the rate of identification of food allergy and lead to improved effectiveness of allergen avoidance.²³ Notably, the presence of GERD does not exclude the diagnosis of EE or food allergy.

TREATMENT FOR EE

A trial of specific food antigen and aeroallergen avoidance is often indicated for patients with atopic EE, and if unsatisfactory or practically difficult (when patients are sensitized to many allergens), a diet consisting of an elemental (amino acid-based) formula is advocated. Interestingly, it has been shown that an elemental diet frequently improves symptoms and reduces the number of eosinophils in the esophageal biopsies of patients with primary EE (allergic or nonallergic subtypes). Patients on elemental diets frequently require placement of a gastrostomy tube in order to achieve adequate caloric intake. Glucocorticoids have also proved effective. Systemic steroids are used for acute exacerbations, and topical steroids provide long-term control.²⁴ When using topical steroids we recommend metered-dose inhalers without spacers. The patient is instructed to swallow the dose to promote deposition on the esophageal mucosa. Topical fluticasone lowers the level of eosinophils, CD3⁺ cells, and CD8 cells in the proximal and distal esophagus,²⁵ and improves symptoms.²⁰ Side effects of inhaled glucocorticoids (e.g., adrenal suppression) are less likely with swallowed fluticasone, as this drug undergoes extensive first-pass metabolism in the liver. However, local esophageal candidiasis may occur.²⁵ In patients unable to use inhalers, an oral suspension of budesonide can be used.²⁶ Even if GERD is not present, neutralizing gastric acidity (with proton pump inhibitors) may improve symptoms and esophageal pathology. Looking to the future, anti-IgE, anti-IL5 or anti-IL13 antibodies are being assessed in clinical trials and animal models.^{27,28,29}

PROGNOSIS FOR EE

It appears that EE requires prolonged treatment. Although the natural history of EE has not been extensively followed, it is not uncommon for children with EE to have a parent with long-standing esophageal strictures. In some cases, esophageal biopsies reveal long-standing EE in these parents. Typically symptoms occur sequentially, with feeding problems, vomiting, abdominal pain, dysphagia, and food impaction occurring with increasing age.³⁰ Thus, it seems likely that, left untreated, chronic EE can progress to esophageal scarring and dysfunction. The risk for the development of Barrett's esophagitis is unknown, but of concern. Patients with EE are at increased risk for developing other forms of EGID; thus, routine surveillance of the entire gastrointestinal tract by endoscopy is warranted.

■ EOSINOPHILIC GASTRITIS AND GASTROENTERITIS ■

In contrast to the esophagus, the stomach and intestine have readily detectable baseline eosinophils under healthy conditions, making diagnosis of eosinophilic gastritis, enteritis, and gastroenteritis more complex than that of EE. These diseases are characterized by selective infiltration of eosinophils in the stomach and/or small intestine, with variable involvement of the esophagus and/or large intestine. Many disorders are accompanied by eosinophil infiltration in the stomach, including parasitic and bacterial infections (including *Helicobacter pylori*), IBD, HES, myeloproliferative disorders, periarteritis, allergic vasculitis, scleroderma, drug injury, and drug hypersensitivity. Similar to EE, these disorders are classified into primary and secondary (Table 46.2). Primary eosinophilic enteritis, gastritis, and gastroenteritis have also been called idiopathic or allergic gastroenteropathy. Primary eosinophilic gastroenteritis is subcategorized based on the level of histological involvement into mucosal, muscularis and serosal forms. Of note, endoscopic biopsy can be normal in patients with the muscularis and/or serosal subtypes.

ETIOLOGY OF EOSINOPHILIC GASTRITIS AND GASTROENTERITIS

Although these diseases are idiopathic, an allergic mechanism has been suggested in some patients, whereas elevated total IgE and food-specific IgE is detectable in most patients. On the other hand, no specific IgE is found in syndromes with focal erosive gastritis, enteritis, and occasionally esophagitis with prominent eosinophilia, such as the dietary (food) protein-induced enterocolitis and dietary protein enteropathy. Although most patients have positive skin tests to a variety of food antigens, they do not have typical anaphylactic reactions, suggesting a delayed form of food hypersensitivity syndrome. Indeed, eosinophilic gastroenteritis (involving the esophagus, stomach, and intestine) can be induced by feeding enteric-coated allergen beads to sensitized mice,³¹ who go on to develop eosinophil-associated gastrointestinal dysfunction, including gastromegaly, delayed food transit, and weight loss.³² Ultrastructural analysis of intestinal tissue suggested that the eosinophils were mediating axonal necrosis, as observed in patients with intestinal eosinophilia associated with IBD. Notably, mast cells are also increased in EGID and may play a critical role in the pathogenesis of allergic diarrhea.³³ In clinical studies, increased secretion of IL-4 and IL-5 by peripheral blood T cells has been reported in patients with eosinophilic gastroenteritis. Furthermore, T cells derived from the lamina propria of the duodenum of patients with EGID preferentially secrete Th2 cytokines (especially IL-13) when stimulated with milk proteins. IgA deficiency has also been associated with eosinophilic gastroenteritis and could be related to the increased rate of atopy in these patients or to occult gastrointestinal infection.

CLINICAL AND DIAGNOSTIC STUDIES FOR EOSINOPHILIC GASTRITIS AND GASTROENTERITIS

In general, these disorders present with a constellation of symptoms related to the degree and area of the gastrointestinal tract affected. The mucosal form of eosinophilic gastroenteritis (the most common variant) is characterized by vomiting, abdominal pain (which may mimic acute appendicitis),

diarrhea, blood loss in stools, iron-deficiency anemia, malabsorption, protein-losing enteropathy and failure to thrive. In the muscularis form, thickening of the bowel wall may result in gastrointestinal obstructive symptoms mimicking pyloric stenosis or other causes of gastric outlet obstruction. The serosal form is characterized by exudative ascites.

There are no standards for the diagnosis of eosinophilic gastritis or gastroenteritis, but the presence of elevated eosinophils in biopsy specimens from the gastrointestinal tract wall, infiltration of eosinophils within intestinal crypts and gastric glands, lack of involvement of other organs, and exclusion of other causes of eosinophilia support a diagnosis of eosinophilic gastroenteritis. Patients with eosinophilic gastritis may have micronodules (and/or polyposis) at endoscopy, and these lesions often contain aggregates of lymphocytes and eosinophils. Food allergy and peripheral eosinophilia may be present but are not required for diagnosis.

TREATMENT OF EOSINOPHILIC GASTRITIS AND GASTROENTERITIS

Eliminating foods implicated by skin-prick or RAST testing has variable results, but complete resolution is generally achieved with amino acid-based elemental diets. Once remission has been achieved by dietary modification, specific food groups are slowly reintroduced (at ~3-week intervals for each food group) and endoscopy is performed every 3 months to identify sustained remission or disease flares. Drugs such as cromoglycate, montelukast, ketotifen, suplatast tosilate, mycophenolate mofetil (an inosine monophosphate dehydrogenase inhibitor), and 'alternative Chinese medicines' have been advocated but are not generally successful, although successful long-term remission of eosinophilic gastroenteritis has been reported following montelukast treatment. Other management includes systemic and topical steroids, noncorticosteroid therapy, management of other EGID complications (such as iron deficiency and anemia) and the management of therapeutic toxicity.³⁴ Anti-inflammatory drugs (systemic or topical steroids) are the main therapy where diet restriction is not feasible or has failed to improve the disease. For systemic steroid therapy, a course of 2–6 weeks of therapy with relatively low doses seems to work better than a 7-day course of burst glucocorticoids. Various topical glucocorticoid preparations are designed to deliver drugs to specific segments of the gastrointestinal tract (e.g., budesonide tablets [Entocort EC] targeted to the ileum and proximal colon). As with asthma, topical steroids have a better risk–benefit risk ratio than systemic steroids. Currently, trials are in progress with anti-IL-5 and anti-IgE.^{28,29} In severe cases refractory to or dependent on glucocorticoid therapy, intravenous alimentation or immunosuppressive anti-metabolite therapy (azathioprine or 6-mercaptopurine) may help. Finally, even if GERD is not present, neutralization of gastric acidity (with proton pump inhibitors) can improve symptoms and the degree of esophageal and gastric pathology.

PROGNOSIS OF EOSINOPHILIC GASTRITIS AND GASTROENTERITIS

The natural history of eosinophilic gastritis, enteritis, and gastroenteritis is not well documented; however, they are often chronic waxing and waning disorders. Notably, the involved gastrointestinal segments often vary from time to time. In patients with clear food antigen-induced disease, abnormal levels of circulating IgE and eosinophils often serve as markers for tissue involvement. As these diseases can often be a manifestation of another primary disease process, routine surveillance of the

cardiopulmonary system is recommended. When the disease presents in infancy and specific food sensitization can be identified, remission is likely by late childhood.

EOSINOPHILIC COLITIS

Eosinophils accumulate in the colon in a variety of disorders, including eosinophilic gastroenteritis, allergic colitis of infancy, infections (including pinworms and dog hookworms), drug reactions, vasculitis (e.g., Churg–Strauss syndrome), and IBD. Allergic colitis in infancy (also known as dietary protein-induced proctocolitis of infancy syndrome) is the most common cause of bloody stools in the first year of life. Similar to other EGID, these disorders are classified into primary and secondary (Table 46.2).

ETIOLOGY OF EOSINOPHILIC COLITIS

In contrast to other EGIDs, eosinophilic colitis is not usually IgE-associated. Some studies point to a T lymphocyte-mediated process, but the exact immunologic mechanisms responsible for this condition remain unclear. Allergic colitis of infancy may be an early expression of protein-induced enteropathy or protein-induced enterocolitis syndrome. Cow's milk and soy proteins are the foods most frequently implicated, but other food proteins can also provoke it. Interestingly, this condition may more commonly occur in infants who are exclusively breastfed, and can even occur in infants fed with protein hydrolysate formulas.

CLINICAL AND DIAGNOSTIC STUDIES FOR EOSINOPHILIC COLITIS

Similar to eosinophilic gastroenteritis, the symptoms of eosinophilic colitis vary depending on the degree and location of tissue involvement. Although diarrhea is a classic symptom, symptoms that can occur independent of diarrhea commonly include abdominal pain, weight loss, and anorexia. There is a bimodal age distribution, the infantile form presenting with a mean age at diagnosis of ~60 days, and the other group presenting during adolescence and early adulthood. In infants, bloody diarrhea precedes diagnosis by several weeks and anemia due to blood loss is not uncommon. Most infants affected do not have constitutional symptoms and are otherwise healthy. On endoscopic examination, patchy erythema, loss of vascularity and lymphonodular hyperplasia are seen; findings are mostly localized to the rectum, but can affect the entire colon. Histological examination often reveals preservation of mucosal architecture, with focal aggregates of eosinophils in the lamina propria, crypt epithelium and muscularis mucosa, and occasionally, multinucleated giant cells in the submucosa. There is no single gold standard diagnostic test, but peripheral blood eosinophilia or eosinophils in the stool are suggestive of eosinophilic colitis.

TREATMENT OF EOSINOPHILIC COLITIS

Treatment of eosinophilic colitis varies according to the disease subtype. For example, eosinophilic colitis of infancy is generally a benign disease. Upon withdrawal of the offending protein trigger in the diet, the gross blood in the stools usually resolves within 72 hours, but occult blood loss can persist longer. Treatment of eosinophilic colitis in older patients usually requires medical management, as IgE-associated triggers are rarely

identified. Drugs such as cromoglycate, montelukast, and histamine receptor antagonists are rarely effective. Anti-inflammatory drugs, including aminosaliclates and glucocorticoids (systemic or topical steroids), are commonly used and appear to be efficacious, but careful clinical trials have not been conducted. Several forms of topical glucocorticoids are designed to deliver drugs to the distal colon and rectum, but eosinophilic colitis typically also involves the proximal colon. In severe cases, refractory or dependent upon systemic glucocorticoid therapy, intravenous alimentation or immunosuppressive antimetabolite therapy (azathioprine or 6-mercaptopurine) are alternatives.

PROGNOSIS FOR EOSINOPHILIC COLITIS

Eosinophilic colitis presenting in the first year of life has a very good prognosis, with the vast majority of patients able to tolerate the culprit food(s) by 1–3 years of age. An association between allergic colitis and the later development of IBD has been reported, but remains controversial. The prognosis for eosinophilic colitis developing in later life is more guarded. As with eosinophilic gastroenteritis the natural history has not been documented, and this disease is considered to be a chronic waxing and waning disorder. Because eosinophilic colitis can often be a manifestation of other disease processes, routine surveillance of the cardiopulmonary system and regular upper and lower gastrointestinal endoscopy are recommended.

CONCLUSION

In a variety of medical conditions, eosinophils accumulate in the gastrointestinal mucosa and cause injury. EGID are being recognized more frequently; they have strong genetic and allergic components, and share clinical and immunopathogenic features with asthma. EGID are associated with a variety of nonspecific common gastrointestinal symptoms and laboratory findings, making their diagnosis dependent on microscopic examination of gastrointestinal biopsy samples. Clinical and experimental models indicate that eosinophils have potent proinflammatory effects mediated by their cytotoxic secondary granule constituents and various lipid mediators and cytokines. In Th2-associated gastrointestinal inflammatory conditions, eosinophilia in the lamina propria is IL-5 and eotaxin dependent. Moreover, eosinophil accumulation in the esophagus can be induced experimentally by delivery to the lungs of aeroallergens or Th2 cytokine (IL-13) (Fig. 46.2). Based on these results, several new therapeutic approaches are now being developed for EGID, including humanized anti-IL-5, the tyrosine kinase inhibitor imatinib mesylate, eotaxin-3 blockers, CCR3 antagonists, and IL-4/IL-13 inhibitors. Although much progress has been made concerning gastrointestinal eosinophils and EGID, there is still a paucity of knowledge compared with other cell types and gastrointestinal diseases that may be even less common (e.g., IBD). A better understanding of the pathogenesis and treatment of EGID will emerge by combining comprehensive clinical and research approaches involving experts in the fields of allergy, gastroenterology, nutrition, and pathology.

ACKNOWLEDGEMENTS

The author would like to thank the numerous colleagues who have contributed to the body of information presented in this review, including Drs Simon Hogan, Anil Mishra, Philip Putnam, Amal Assa'ad,

Fig. 46.2 Summary of pathogenesis and treatment strategies for EGID. Pathological increases in eosinophils occur in EGID, a series of disorders strongly associated with food and aeroallergen sensitization. EGID is generally a tissue-specific problem compared to HES (which has a proclivity to involve the heart, lungs, and skin); however, there can be overlap, especially when EGID is accompanied by marked blood eosinophilia. Whereas EGID may simultaneously involve multiple gastrointestinal segments (e.g., eosinophilic gastroenteritis), specific regions of the gastrointestinal tract may be selectively involved, as in eosinophilic esophagitis (EE), a disease mechanistically linked with eosinophilic airway inflammation (asthma). Recent studies have implicated an important role for the cytokines IL-5, IL-13, and eotaxins with various manifestations of EGID. Based on these collective findings, clinical intervention strategies that are currently being investigated for EGID include allergen avoidance, and therapy with anti-IL-5 and anti-IL-13 humanized antibodies, CCR3 antagonists, and imatinib mesylate. This figure also lists common symptoms of EGID, triggering factors, diagnosis and management. (Adapted from Rothenberg ME, Mishra A, Brandt EB, Hogan SP. Allergic disorders of the eye

Virginia L. Calder, Melanie Hingorani, Sue L. Lightman

47

Considerable progress has been made in our understanding of immune responses at the ocular surface and their role in the pathogenesis of allergic diseases affecting corneal and conjunctival tissues. Allergic disorders of the eye range from the common, milder condition seasonal allergic conjunctivitis (SAC), to the rarer but more severe diseases vernal keratoconjunctivitis (VKC) and atopic keratoconjunctivitis (AKC). Whereas in SAC the allergic responses are confined to the conjunctival tissues, in both VKC and AKC the cornea can also be affected, leading to impaired vision. VKC and AKC are immune mediated and require immunosuppressive therapy with steroids and cyclosporine, which can have serious side effects. Extensive immunohistochemical studies have identified differential expression profiles of key cell adhesion molecules, cytokines and cell types in each form of conjunctivitis (see Key Concepts), and the different immunopathogenic mechanisms are under investigation in experimental models. Here we review recent advances in our understanding of the immunopathogenesis of allergic diseases of the eye, with a view to improving treatment options for these potentially blinding diseases.

■ SEASONAL ALLERGIC CONJUNCTIVITIS ■

Ocular allergy is the commonest ocular disorder seen in primary care; seasonal allergic conjunctivitis (SAC) comprises the majority of this. SAC, or hayfever, is a recurrent conjunctivitis that manifests only during the pollen season: its timing (spring, summer or autumn) is dependent on which particular pollen (e.g., tree, grass, weed) is allergenic for that individual. The disorder can occur at any age but is more frequently seen in children and young adults; with advancing age there is a tendency towards a lessening of severity.

Patients present with recurrent seasonal itching, watering, and redness and swelling of the eyes and lids; there may also be increased discharge. Seasonal rhinitis is commonly present and a personal or family history of atopy can often be elicited. During the allergen season, the ocular signs are usually bilateral and symmetrical and range from mild to dramatic. Edema of the lids and conjunctiva often outweighs the degree of hyperemia, giving

a milky or pink appearance to the eye. Usually this is mild, but the swelling may be gross, with inability to open the lids and a ballooning out of the conjunctiva termed chemosis, particularly after exposure to high aeroallergen concentrations or after rubbing of the eye. Eversion of the lids to reveal the tarsal conjunctiva demonstrates some hyperemia and mild infiltration (loss of transparency and thickening) of the conjunctiva with diffuse small inflammatory excrescences known as papillae. Because there is no serious limbal disease or conjunctival scarring, and the cornea is not involved, visual acuity remains normal. Outside the pollen season eye examination is normal.

CONJUNCTIVAL IMMUNOSTAINING IN SAC

SAC involves an immediate (type I) hypersensitivity response; mast cells are the main infiltrating cells in the conjunctiva, with some neutrophils and eosinophils in less than half of symptomatic patients with SAC, but little or no T-cell influx (Fig. 47.1).¹ Relative increases in mucosal mast cells have been identified in the tarsal conjunctiva in SAC.² Mast cells and their secreted products (histamine, proteases, leukotrienes, chemokines, cytokines) are the main orchestrators of the inflammatory response in SAC, although neutrophils and eosinophils are also present and are capable of secreting a range of proinflammatory agents that could augment the inflammation. Immunohistochemical studies of tarsal and bulbar conjunctival biopsy specimens have demonstrated increased expression of ICAM-1 and E-selectin adhesion molecules in SAC compared to controls, but only during the pollen season.³ Outside the pollen season, adhesion molecule levels returned to those of controls. This pattern of expression correlated with the degree of neutrophil or eosinophil infiltration in the bulbar tissue, suggesting that cellular recruitment is mast-cell mediated (see Clinical Pearls).

THERAPY

General measures may provide effective relief, particularly when the disease is not severe. Commonsense measures include minimizing pollen exposure by avoiding grassy fields or rural areas, keeping windows (house and car) shut and remaining indoors, especially on days with a high pollen

Fig. 47.1 Cross-section of conjunctival tissue biopsy, showing the cell processes involved in VKC- vs AKC-affected tissues.

count. Cold compresses and ocular lubricants (artificial tears) relieve symptoms, particularly itching.

Oral and topical H₁ antihistamines are widely used and provide rapid symptom reduction but have no preventative role and a limited potency, as they only address one arm of the inflammatory mediator response (see Clinical Pearls). Oral antihistamines also treat any concurrent rhinitis, but the onset of ocular action is slower and the local effective concentration is less than for topical therapy. Moreover, oral use exposes the patient to the risk of unwanted systemic effects. They are often used for children, where topical therapy can be difficult, and also at night when their sedative effect can be advantageous. Topical antihistamines are available in combination with a vasoconstrictor (a lower dose of antihistamine can be used as

the two components are synergistic) or as higher-potency antihistamine-only preparations (e.g., levocabastine, emedastine, azelastine). The higher-potency preparations provide a more rapid onset of symptom relief, have a more prolonged action after instillation, and avoid the worry of rebound vasodilatation and potential permanent dilatation of the conjunctival vessels associated with long-term vasoconstrictor use. Topical antihistamine drops, particularly in combination with vasoconstrictors, can cause contact allergic conjunctivitis, which may limit their use in a number of patients.

Of the several topical nonsteroidal anti-inflammatory drugs (NSAIDs) assessed in ocular allergy, ketorolac is the only one currently approved for ocular allergy. NSAIDs offer the advantage of safety, but there have been concerns that their efficacy is not well proven compared to other

Fig. 47.2 Photographs illustrating clinical features of VKC (A) and AKC (B).

established remedies, and there are also concerns about their cost. Topical mast cell inhibitors (e.g., sodium cromoglycate) are the most useful drugs for nonsight-threatening ocular allergy. They have a number of actions that account for their ability to prevent symptoms if used early in the disease and continued throughout the allergen season, including mast cell degranulation, inhibition of leukocyte recruitment, and direct mediator antagonism. One limitation has been the slower onset of symptom relief compared to antihistamines (although this is less of an issue with the newer, high-potency preparations lodoxamide, nedocromil), and some tendency to sting after instillation (possibly less with lodoxamide). They are almost completely safe, though very occasionally they may cause local contact allergy.

Several of the newer topical antihistamines, in particular olopatadine, epinastine and ketotifen, have additional properties, including mast cell inhibition and mediator antagonism. They offer the potential advantage of a rapid onset of action with the preventative and long-term effect of inhibiting mast cell mediator release. Olopatadine and epinastine in particular seem to offer some clinical advantage over antihistamines and

compare well with mast cell inhibitors in allergen challenge models and in clinical trials in SAC.⁴

Topical steroids have a minimal role in SAC, compared to their role in allergic rhinitis and asthma, owing to their potential for ocular adverse effects (see below). They are occasionally used in short courses for severe disease to gain control of inflammation, but their use must be supervised by an ophthalmologist.

■ PERENNIAL ALLERGIC CONJUNCTIVITIS ■

Perennial allergic conjunctivitis (PAC) is the second commonest ocular allergy.⁵ It bears many similarities to SAC, but as the allergens in PAC are present for most or all of the year the disease is present all year round. PAC is most frequent and severe in children and young adults. House dust mites (*Dermatophagoides pteronyssinus*) are the commonest sensitizing allergens, but animal hair and dander, molds and other antigens may be responsible.

The symptoms comprise perennial ocular itch, discomfort, watering, redness, and some discharge. Patients may be able to correlate symptomatology with exposure to, for example, the presence of pets or a particular location. House dust mite allergy sufferers give a history of symptoms being worse in the morning. Approximately one-third have associated allergic rhinitis, and a family or personal atopic history is very common. The clinical appearance is of a mild conjunctival inflammation, and clinical signs may be very slight. The bulbar conjunctiva may be slightly red and edematous, and the tarsal conjunctiva shows mild to moderate hyperemia, infiltration and fine papillae. Lid edema is usually mild. As with SAC, there is no conjunctival scarring, corneal or serious limbal involvement, and so normal visual acuity is maintained.

IMMUNOHISTOLOGICAL STUDIES IN PAC

PAC also involves an immediate-type hypersensitivity response, but because the allergens are present continuously, unlike in SAC, the resultant inflammation is more chronic. Increased numbers of mast cells are detected in both the tarsal conjunctival epithelium and in the substantia propria, with both mucosal and connective tissue mast cell phenotypes.² In addition to mast cells, eosinophils, neutrophils and some T cells are present, suggesting that other cell-mediated processes are likely to be involved, although it is not yet known whether these cells contribute to the chronic inflammation in PAC. In general, little is known about the basic immunological processes occurring within the conjunctival tissues in PAC, and further research is needed.

THERAPY

In house dust mite sensitivity, advice should be provided on mite reduction. Potential manoeuvres include removal of soft furnishings in the bedroom (e.g., carpet, curtains), the use of vacuum cleaners with appropriate filters to perform intensive and regular vacuuming, including the curtains and mattress, use of mite-impermeable mattress and pillow covers, washing bedlinen and curtains at mitocidal temperatures (>55°C), and mitocidal chemicals. For patients with mold sensitivity, dehumidifying devices and mold-killing chemicals may help. For pet allergy, avoidance of the pet may be effective but is often an unpopular option.

The drug therapy of PAC is essentially as recommended for SAC (see above), but as the disease is usually prolonged, the continued use of mast cell inhibitors assumes more importance and antihistamines tend to be used episodically for flares of inflammation. Another consideration when using topical medication is the potential development of ocular

responses to the preservatives, either an allergic response, or direct damage to the ocular surface: hence preservative-free preparations should be used if at all possible.

EXPERIMENTAL MODELS OF ALLERGIC CONJUNCTIVITIS

Conjunctival allergen challenge

This model involves challenging the ocular surface to an allergen in sensitized individuals to artificially induce the ocular allergic response.⁶ Symptoms are similar to those seen in SAC, and therefore the model is useful for investigating the early- and late-phase allergic responses at the ocular surface. During the early phase (20 minutes) increased levels of histamine and tryptase can be detected in tear fluid, suggesting the effector cell population to be predominantly mast cells. At 6 hours (i.e., the late phase) histamine and eosinophil cationic protein levels are elevated, but not tryptase levels, suggesting that basophils and eosinophils are recruited and contribute to the late-phase response.⁷ T cells are also increased, but only in bulbar biopsy specimens. The allergen challenge model is often used to test the efficacy of eye drops.

Experimental murine allergic conjunctivitis

A model of allergic conjunctivitis has been established⁸ in genetically susceptible mice, using an initial footpad sensitization with short ragweed pollen, followed 7–10 days later by conjunctival allergen challenge. An infiltration of mast cells, neutrophils and eosinophils occurs, as well as increased conjunctival chemosis and lid edema. Interestingly, although there is no significant infiltration of T cells, the model is IFN- γ dependent, as it could be inhibited by anti-IFN- γ antibody and could not be induced in IFN- γ -knockout mice.⁹ Furthermore, in IL-12-deficient mice there was significantly less conjunctival inflammation, supporting a role for Th1 cytokines in this model.⁸

VERNAL KERATOCONJUNCTIVITIS

Vernal keratoconjunctivitis (VKC) is a serious ocular allergy of childhood. It constitutes 0.1–0.5% of ocular disease in the developed world but is more common and much more severe in hot dry countries, especially the Middle East, West Africa and the Mediterranean. In the UK, VKC is an unusual, self-limiting, often seasonal ocular allergy that affects children and young adults; there is a male preponderance (85%) and most sufferers have a personal or family history of atopy.

KEY CONCEPTS

PREDOMINATING CELL TYPES IN THE CONJUNCTIVAL TISSUES

- >> In seasonal allergic conjunctivitis, perennial allergic conjunctivitis: mast cells
- >> In vernal keratoconjunctivitis: eosinophils, T cells, neutrophils, mast cells
- >> In atopic keratoconjunctivitis: T cells, eosinophils, neutrophils

CLINICAL PEARLS

SEASONAL ALLERGIC CONJUNCTIVITIS

- >> Seasonal response to allergen (pollen)
- >> Mast-cell mediated
- >> Antihistamines, mast cell inhibitors

The link with atopy and seasonality is less clearly defined in less temperate climates.

The symptoms are worse in the spring and summer, but in severe disease can last all year. Patients complain of marked itching, discomfort or pain, photophobia, stringy discharge, blurred vision, and difficulty opening the eyes in the morning. The ocular signs may be very asymmetrical. Conjunctival signs are maximal in the superior tarsal conjunctiva and limbus, and the heavily inflamed lid may droop (ptosis). The conjunctival surfaces are hyperemic, edematous and infiltrated, and a stringy mucoid discharge is present. The tarsal conjunctiva is densely infiltrated, with papillae that are often giant (>1 mm in diameter, also known as cobblestone papillae). The limbus may show discrete swellings or, less often, diffuse hyperemia and infiltration; the presence of small white chalky deposits (Trantas' dots) is typical of vernal limbitis. In the later stages fine reticular white scarring may be seen, but this does not lead to significant shrinkage and distortion of the ocular surface, in contrast with some other cicatrizing conjunctival diseases (e.g., AKC, see below).

Visual acuity can be affected by involvement of the cornea (keratopathy), which is most marked in the upper third of the cornea owing to greater exposure to toxic inflammatory mediators, not mechanical rubbing by the papillae. At its mildest there is a punctate disturbance of the epithelium, which may coalesce to form a discrete epithelial defect (macroerosion). Deposition of mucus, fibrin and inflammatory debris can then result in the formation of a shallow oval plaque (or shield) ulcer, which repels the hydrophilic tears and the epithelial healing response (Fig. 47.2). Herpetic and bacterial corneal infection may ensue. In the later stages, scarring of the cornea may lead to a permanent reduction in vision. Steroid treatment-related complications and sensory-deprivation amblyopia (because of the young age group) also contribute to the potential for long-term visual loss (see Clinical Pearls).

IMMUNOLOGICAL STUDIES IN VKC

Several studies have identified cells of both innate and adaptive immune responses that are activated during VKC. T lymphocytes and eosinophils predominate, with mast cells, neutrophils and other activated cell types infiltrating the conjunctival epithelium and stroma. Studies of tarsal conjunctival tissue specimens have found increased numbers of activated CD4 T cells, mainly localized to the subepithelial layer of the affected tissue, and increased HLA-DR expression compared to normal subjects.¹⁰ Increased numbers of Langerhans' cells and activated macrophages

(CD68⁺) were also observed. T-cell clones,¹¹ derived from VKC conjunctival tissues, were functionally characterized as Th2 type, and *in situ* hybridization staining demonstrated an upregulation of mRNA for IL-3, IL-4 and IL-5 in VKC in areas of maximum T-cell infiltration, supporting a Th2-cell involvement.¹² VKC tear samples were found to have increased intracellular T-cell expression of IL-4 in 67% of specimens,¹³ and increased levels of IL-4, IL-10, IFN- γ , eotaxin and TNF- α compared to controls.¹⁴ Comparison of conjunctival biopsy specimens from VKC patients against controls showed increased expression of RANTES, eotaxin, monocyte chemotactic protein (MCP)-1 and MCP-3,¹⁵ reflecting the range of inflammatory cells present. VKC conjunctival expression of the chemokine receptor CXCR3 was found to be specifically localized to T cells,¹⁶ and the CXC chemokine Mig was highly expressed, suggesting an important role for this ligand in recruitment of activated T cells.¹⁷

MANAGEMENT OF VKC

The treatment goals of VKC are to obtain adequate symptom control and to prevent both disease and iatrogenic complications that might permanently reduce visual acuity, bearing in mind that the disease is likely to remit spontaneously before adulthood. In cases where there appears to be pollen sensitivity, advice on pollen avoidance should be given, similar to that for SAC (see above). Simple measures including cold compresses, ocular lubricants and mucolytic drops may help. Antihistamines have a very limited role in the disease, and immunotherapy is not helpful.

Mast cell inhibitors are effective in VKC and should be maintained throughout the period of active inflammation, two to four times daily depending on the severity of disease and which preparation is used. Lodoxamide and nedocromil may offer some slight extra potency in clinical control. Patients with mild disease may be able to discontinue therapy during the winter months. It is important to emphasize to patients and parents that mast cell inhibitors are safe and must be continued when using steroids, in order to minimize the dose of steroids required and hence the risk of steroid complications. The role of other agents such as olopatadine in VKC is not yet established.

Steroids are highly potent controllers of allergic inflammation and are frequently required in VKC. Unfortunately, they carry a significant risk of ocular adverse effects, specifically ocular hypertension, glaucoma, and cataract, and they worsen infective keratitis. This is a particular worry in children, where examination to detect these complications may be difficult (e.g., tonometry for intraocular pressure) and also where

CLINICAL PEARLS

VERNAL KERATOCONJUNCTIVITIS

- >> A chronic conjunctival inflammation with seasonal exacerbations
- >> Eosinophils and T cells infiltrate the conjunctival tissues
- >> Usually affects young males
- >> Cornea can be affected
- >> Increased expression of Th2 cytokines, adhesion molecules, eotaxin
- >> Often requires steroids and topical cyclosporine

CLINICAL PEARLS

ATOPIC KERATOCONJUNCTIVITIS

- >> The most severe form of allergic eye disease
- >> Affects adults with atopic dermatitis or asthma
- >> Predominant infiltration of T cells expressing IFN- γ in severe cases
- >> Cornea can be affected, often by secondary infections
- >> Requires steroids and cyclosporine

iatrogenic adverse effects may have long-term visual consequences well after the disease has regressed spontaneously. To minimize the risk of adverse effects, other therapies (especially mast cell inhibitors, but also cyclosporine) should be used, and steroids can be prescribed in short, sharp, rapidly tapering doses during episodes of high disease activity or significant keratopathy. In addition, it is advisable to use surface-acting preparations with a reduced intraocular effect (e.g., fluoromethalone, rimexolone), although they are not currently available in the preservative-free formulations that may be required for high-frequency use. Systemic steroids are also sometimes utilized, but expose the patient to numerous potential adverse effects. Supratarsal injections of steroids, either long-acting (triamcinolone) or short-acting (e.g., dexamethasone) may be very effective, but these are not surface-acting agents and therefore do carry a significant risk of local side effects; moreover, unlike drops, neither the treatment effect nor any adverse effects can be suddenly terminated if problems arise.

Cyclosporine is a specific T-cell inhibitor but also has a number of other inhibitory effects (e.g., on eosinophils, mast cells) that are likely to contribute to its effectiveness in ocular allergic therapy. Topical cyclosporine 2% dissolved in oil (usually maize oil) has been used to great effect in VKC¹⁸ and is particularly effective in treating corneal complications and as a steroid-sparing agent. It has no systemic adverse effects and none of the serious ocular complications of steroids, so that generally it may be used safely long-term. It may cause temporary lid skin and corneal surface irritation, which resolves on drug cessation. However, there are difficulties with its use. It can produce intense post-instillation stinging that can prevent eye opening for some time, and the oil base can cause symptomatic visual smearing that can persist for some hours and may be enough to limit driving. In addition, drops are not commercially available at this concentration, and must be obtained from the few hospital pharmacies that manufacture on-site in a labor- and time-intensive process. The commercially available and well-tolerated 0.05% cyclosporine emulsion marketed for dry eye has unfortunately not proved efficacious in VKC. Some units have obtained the unlicensed 0.2% veterinary ointment on a named-patient basis and claim benefit.

Surgical interventions are sometimes required in VKC for the corneal manifestations; surgical or excimer laser superficial keratectomy may be used in conjunction with medical inflammation control for plaque ulcer; rarely corneal grafting may be required for scarring. Surgical removal of giant papillae or for conjunctival reconstruction is not generally recommended.

EXPERIMENTAL MODEL OF VKC

In genetically susceptible rats and mice, immune-mediated blepharoconjunctivitis is inducible by subcutaneous immunization with short ragweed pollen followed by conjunctival allergen challenge at day 10. In this model a significant eosinophilia is found 24 hours after challenge, and this has therefore been used as a model for studying eosinophil infiltration as found in VKC. It can also be induced by adoptively transferring Th2, but not Th1, T cells, demonstrating that eosinophil infiltration is Th2 mediated.¹⁹ Similarly, transfer of antigen-specific IgE is less potent at inducing conjunctival eosinophil infiltration than transfer of antigen-primed splenocytes.²⁰ Modulation of co-stimulatory molecules significantly affected conjunctival eosinophil infiltration, suggesting that this may be a possible target for treating VKC.²¹

■ ATOPIC KERATOCONJUNCTIVITIS ■

Atopic keratoconjunctivitis (AKC) is the least common but most serious of the ocular allergies. It is a highly symptomatic disorder with severe itching, pain, watering, stickiness and redness of the eyelids and eye (see Clinical Pearls).²²

AKC is a lifelong condition that affects adults with systemic atopic disease, particularly atopic dermatitis. The usual age of onset is in the late teens; occasionally the disease can begin in childhood. In contrast to VKC, the disease is persistent and may be relentlessly progressive. There is usually facial atopic dermatitis involving the eyelids. The lid margins show severe blepharitis (chronic inflammation of the lash follicles and meibomian glands) and are thickened, hyperemic, posteriorly rounded, and sometimes keratinized. The lid anatomy may be distorted with ectropion (outwardly turning eyelid), entropion (inwardly turning eyelid), trichiasis (inturning lashes), loss of lashes and notching. The whole conjunctiva is affected and shows intense infiltration, papillae (which may be giant), and sometimes scarring with linear and reticular white scar tissue, lid-to-conjunctiva adhesions (symblepharon), and shrinkage or loss of the conjunctival sac and secondary lid distortions. Marked limbal inflammation may develop and Trantas' dots may occur. The disease may spare the cornea, in which case the alternative name atopic blepharoconjunctivitis can be used; in this form of the condition the overall inflammation is generally less severe.

The cornea may be directly involved by the inflammatory process or may be damaged secondary to the extensive changes in the usually protective ocular surface by processes such as continual mechanical trauma, reduced lid protection, or severe loss of conjunctival tear production. Significant reduction in visual acuity due to corneal involvement occurs in 40–70% of cases. Keratopathy may consist of punctate and macroscopic epithelial defects, filamentary keratitis, plaque ulcer, progressive scarring, neovascularization (with or without lipid deposition), thinning and secondary corneal infections (herpetic, bacterial and fungal). Associations are recognized between AKC and eye rubbing, keratoconus, atopic cataract and retinal detachment.

IMMUNOLOGICAL STUDIES IN AKC

In AKC the predominant cell types that infiltrate the conjunctival tissues are T cells, eosinophils and neutrophils (Fig 47.1 and Key Concepts). As in VKC, increased numbers of activated CD4 T cells, HLA-DR expression, and cells of the monocyte/macrophage lineage are found in conjunctival biopsy specimens in AKC,¹⁰ as well as mRNA expression of IL-3, IL-4 and IL-5 in the stroma. However, unlike VKC, there is a significant increase in the expression of IL-2 mRNA, and in numbers of IFN- γ -expressing T cells, suggesting a more Th1-type inflammation in this most severe of the ocular allergic diseases.¹² The production of proinflammatory cytokines by infiltrating conjunctival T cells could provide a mechanism whereby local tissue resident cells such as conjunctival fibroblasts become involved, as collagen deposition and conjunctival tissue remodeling in chronic allergic eye disease are considerable. Thus cultured human conjunctival fibroblasts have been found to respond to exogenously added IL-4, IL-13, IFN- γ and TNF- α by producing collagen and by secreting other factors, including eotaxin-1,²³ a potent chemokine for eosinophils. In severe forms of AKC, increased tear levels of eotaxin were found to correlate with increased numbers of eosinophils in tears,²⁴ although the cellular source of the eotaxin was not identified.

THERAPY

The therapy of AKC is not only symptomatic, but should also attempt to modify and reduce serious sight-threatening sequelae. The topical treatment of the ocular surface is similar to that for VKC, in that some general therapy may help; antihistamines are not useful; mast cell inhibitors are continued long term; and steroid and cyclosporine drops are often required. However, the disease is generally less episodic than VKC and so long-term steroid use is often needed and steroid-related complications are more problematic. In particular, herpetic keratitis, which is more common and severe in AKC, can be potentiated by topical steroids. Facial and lid dermatitis should be actively managed, if necessary in conjunction with a dermatologist, and lid margin inflammation (blepharitis) should be treated with hot compresses followed by lid hygiene, topical antibiotic and/or steroid preparations, and systemic low-dose antibiotics (especially tetracyclines), all of which will lessen the need for anti-inflammatory and immunosuppressive therapy.

Systemic therapy can be necessary in severe cases, particularly when surgical therapy is undertaken, and includes steroids, cyclosporine and sometimes other immunosuppressive agents such as mycophenolate mofetil, but all carry a risk of serious side effects and also affect atopic disease elsewhere, so consultation with physicians dealing with these other aspects is advisable.

A significant number of patients require ocular surgery, either as a consequence of the disease or because of the associated keratoconus. Surgery for AKC includes both elective procedures and emergency interventions, and may consist of corneal gluing, patch grafts, corneal transplants (partial or full thickness), conjunctival reconstruction, amniotic membrane grafts and limbal transplantation. These are generally high-risk procedures and often require support with systemic immunosuppression.

In summary, allergic disorders of the eye range in severity and duration. Studies over the past 10 years have greatly increased our understanding of the cellular mechanisms involved. Although the therapeutic options for treating mast cell-mediated forms of allergic conjunctivitis have greatly improved, there is still a need to find alternative, safer therapies for the more severe and chronic forms.

Drug hypersensitivity

Werner J. Pichler

48

Drug-induced adverse reactions are common and may be classified into those that represent predictable side effects due to pharmacological actions of the drug and those that are not predictable, comprising idiosyncratic reactions due to some individual predisposition (e.g., an enzyme defect), and hypersensitivity reactions.¹ Drug hypersensitivity reactions account for about one-sixth of all adverse drug reactions. They comprise allergic and so-called pseudoallergic reactions, the latter involving direct stimulation of immune effector cells, and thus imitating an allergic reaction, but without detectable reactions of the adaptive immune system.

Drug hypersensitivity can present in many different ways, some of which are quite severe and even fatal.^{2,3} The most common allergic reactions occur in the skin and are observed in about 2–3% of hospitalized patients.^{4,5} Any drug can elicit hypersensitivity reactions, but antibiotics and antiepileptics are the drugs most frequently responsible. The risk of sensitization and the severity of clinical symptoms depend on the state of immune activation of the individual, the dose and duration of treatment, female sex, and immunogenetic predisposition (in particular human leukocyte antigen (HLA)-B-alleles), while a pharmacogenetic predisposition has seldom been detected.

Epicutaneous application of a drug clearly increases the risk of sensitization compared to oral or parenteral treatment. Atopy – defined as the genetic predisposition to mount an immunoglobulin E (IgE) response to inhaled or ingested innocuous proteins – is not normally associated with a higher risk of drug hypersensitivity, but an atopic predisposition may prolong the detectability of drug-specific IgE in the serum.⁶

■ IMMUNE RECOGNITION OF DRUGS ■

THE HAPTEN AND PROHAPTEN CONCEPT

The recognition of small molecules like drugs by B and T cells is usually explained by the hapten concept.^{1,7} Haptens are chemically reactive small molecules (mostly <1 kDa) that are able to undergo a stable,

covalent binding to a larger protein or peptide (Chapter 6). Only by this modification of a protein or peptide does a small molecule become antigenic (Fig. 48.1). Modification can affect soluble autologous proteins (e.g., albumin), cell-bound proteins (e.g., integrins) or the peptide embedded in the major histocompatibility complex (MHC) molecule itself. Consequently, a wide array of immune responses can develop to a hapten, as many different antigens are formed, which induce different types of immune responses (Fig. 48.1A). This can lead to a great heterogeneity of clinical pictures. Indeed, drug hypersensitivity is today the great imitator of diseases, having taken over this role from syphilis, which was the great imitator a century ago.

An immune response may only arise if the hapten is also able to stimulate innate immunity. This could occur by covalent binding to cell surface structures, which might induce expression of CD40 on dendritic cells.

A typical hapten is penicillin G, which binds covalently to ϵ -amino groups on lysine residues within soluble or cell-bound proteins, thereby modifying them and eliciting B- and T-cell reactions. The hapten may also bind directly to the immunogenic peptide presented by the MHC-molecule. In this case no processing is required (Fig. 48.1A). Direct alteration of the MHC molecule is also possible, but evidence from mouse models suggests that this is less frequent.⁸

Many drugs are not chemically reactive but are still able to elicit immune-mediated side effects. The prohaptens hypothesis tries to reconcile this phenomenon with the hapten hypothesis by stating that a chemically inert drug may become reactive upon metabolism^{1,7,9} (Fig. 48.1B). Sulfamethoxazole is a prototype prohaptens. It is not chemically reactive itself but becomes immunogenic by intracellular metabolism. Cytochrome p450-dependent metabolism leads to sulfamethoxazole-hydroxylamine, which can be found in the urine and is easily transformed to the highly reactive sulfamethoxazole-nitroso by oxidation. The latter is chemically highly reactive and binds covalently to proteins/peptides (Fig. 48.1B), forming neoantigens. The resulting clinical picture can be as variable as with haptens: sulfamethoxazole is known to cause many different diseases, affecting many organs. These side effects are mediated by antibodies and/or T cells. On the other hand,

Fig. 48.1 Hapten and prohaptent-concept and the noncovalent drug presentation to T cells. **(A)** Haptens: drugs are haptens if they can bind covalently to molecules, either soluble or cell-bound (e.g., penicillin G). They can even bind directly to the immunogenic major histocompatibility complex (MHC)–peptide complex on antigen-presenting cells (APC), either to the embedded peptide or to the MHC molecule itself. Thus, the chemical reactivity of haptens leads to the formation of many distinct antigenic epitopes, which can elicit both humoral and cellular immune responses. **(B)** Prohaptens: other drugs are prohaptens, requiring metabolic activation to become haptens (chemically reactive). The metabolism leads to the formation of a chemically reactive compound (e.g., from sulfamethoxazole (SMX) to the chemically reactive form SMX-NO). The resulting intake may lead to modification of cell-bound or soluble proteins by the chemically reactive metabolite, similar to a real hapten. **(C)** The p-i-concept (pharmacological interaction with immune receptors): drugs are often designed to fit into certain proteins/enzymes to block their function. Some drugs may happen also to bind into some of the available T-cell receptors. Under certain conditions (see text) this drug–T-cell receptor interaction may lead to an immune response of the T cell with a ‘fitting’ T-cell receptor. For a full T-cell stimulation by such an inert drug, an interaction of the T-cell receptor with the MHC molecule is required. This type of drug stimulation results in an exclusive T-cell stimulation. (Modified from Pichler WJ. Delayed drug hypersensitivity reactions. *Ann Intern Med* 2003; 139: 683–693, with permission from the American College of Physicians.)

transformation of a prohaptent to the reactive hapten may occur exclusively in the liver or kidney and may thus cause an isolated hepatitis or interstitial nephritis.

THE P-I CONCEPT

Recently, a third possibility, namely a pharmacological interaction of drugs with immune receptors (p-i concept, Fig. 48.1C) has been elaborated.^{10,11} According to this concept, chemically inert drugs, incapable of covalently binding to peptides or proteins, can nevertheless directly activate T cells, if they happen to fit into any of the innumerable different T-cell receptors (TCRs) available. This interaction may result in selective T-cell stimulation, similar to the activation by peptide MHC. This process does not require biotransformation (to a chemically reactive compound) and thus the generation of a drug (hapten)-specific immune

response to the hapten–carrier complex is not required. After drug binding to the TCR an additional MHC interaction with the TCR is required for full activation. It is assumed that the drug activates previously primed memory T cells with a certain peptide specificity and a lower threshold of reactivity than naïve T cells. This threshold might be further lowered by a massive immune stimulation of T cells such as occurs during generalized herpes or human immunodeficiency virus (HIV) infection, but also during exacerbations of autoimmune diseases. This would explain the high occurrence of drug hypersensitivity in these diseases.

The p-i concept radically changes our understanding of drug-induced hypersensitivity reactions, but may in fact explain some unusual features of drug hypersensitivity that are not explained by the hapten concept. According to the p-i concept, the symptoms are the consequence of a pharmacological reaction of immunologically competent cells, and not the result of a specific immune response. This can explain the symptoms

at the first encounter with the drug, without a sensitization phase, the higher risk of drug hypersensitivity in generalized viral infections, and some peculiar *in vitro* and *in vivo* features of drug-elicited immune responses, which are reminiscent of superantigenic stimulation (Chapter 6) rather than a coordinated immune response leading to a massive overstimulation.¹¹ Detailed analysis of T-cell stimulation by sulfamethoxazole, phenytoin, and carbamazepine suggests that the hapten and p-i concepts might often occur together.

■ CLASSIFICATION OF DRUG HYPERSENSITIVITY REACTIONS ■

Drug hypersensitivity reactions can cause many different diseases. To account for this heterogeneity and to explain the various clinical pictures, Gell and Coombs⁴³ classified drug hypersensitivity as well as other immune reactions in four categories, termed type I–IV reactions.

This classification has been revised to take into account the heterogeneity of T-cell functions⁷ and the interdependence of these reactions since, for example, the maturation of B cells to IgE- or IgG-producing plasma cells depends on T-cell help. Thus, type I and type IVb reactions often occur together, as do type II or III with type IVa reactions, and the clinical picture is probably dominated by the prevalent immune reaction.

ANTIBODY-MEDIATED DRUG HYPERSENSITIVITY REACTIONS

As outlined above (Fig. 48.1), hapten-like features of a drug allow the modification of soluble and cell-bound proteins. The natural reaction of the immune system to such antigens is the development of a humoral immune response. Consequently, if a humoral immune response develops, the eliciting drug should have hapten-like features forming hapten–carrier complexes, or itself be protein-bearing “foreign” determinants (e.g., chimeric antibodies). Indeed, the majority of drugs able to elicit IgE-mediated allergies are known haptens, or contain foreign antigenic structures (Table 48.1).

TYPE I (IgE-MEDIATED) ALLERGIES

The IgE system is geared to react to small amounts of antigens. It achieves this extraordinary sensitivity by the ubiquitous presence of mast cells armed with high-affinity Fcε receptors (Fcε-RI), to which allergen/drug-specific IgE is bound. Very small amounts of a drug are apparently sufficient to interact and stimulate these receptor-bound IgE molecules, as occasionally even skin tests with drugs can elicit systemic reactions. Upon cross-linking the Fcε-RI, various mediators (histamine, tryptase, leukotrienes, prostaglandins, tumor necrosis factor-α (TNF-α)) are released, which cause the symptoms (Chapters 22 and 42).

IgE-mediated reactions to drugs are usually thought to depend on the prior development of an immune response to a hapten–carrier complex: B cells need to mature into IgE-secreting plasma cells, and T cells help in this process by interacting with B cells (i.e., CD40–CD40L interaction) and by releasing interleukin-4 (IL-4)/IL-13, which are switch factors for IgE synthesis. This sensitization phase is asymptomatic and may have occurred during a previous course of treatment. Upon renewed contact with the drug, a hapten–carrier complex is formed again, which then cross-

links preformed drug-specific IgE on mast cells. The drug itself is normally too small to cross-link two adjacent IgE molecules (Fig. 48.2A).

These reactions were at one time erroneously considered to be dose-independent, as sometimes very small amounts can already cause severe reactions. But further diminishing the dose – as done in desensitization procedures – demonstrates that these reactions are *clearly dose-dependent*.

In sensitized individuals the reaction can start within seconds after parenteral administration, and minutes after oral intake (Fig. 48.2A). Anaphylactic shock can occur within 15 minutes, and asphyxia due to laryngeal edema between 15 and 60 minutes. The initial symptoms may be palmar, plantar, genital, or axillary itch, which should be seen as an alarm sign, as it often heralds a possibly severe, anaphylactic reaction, following rapidly within minutes: The skin becomes red (diffuse erythema), often first affecting the trunk, and later the whole body. In the next ~30–60 minutes an urticaria may appear, together with swelling of the periorbital, perioral, and sometimes genital areas (Fig. 48.3). Asphyxia may account for 60% of anaphylaxis-related deaths: laryngeal swelling should be suspected if the voice becomes hoarse, and the patient has difficulty speaking and swallowing due to tongue swelling. Patients may also complain of chest tightness and dyspnea – signs of acute bronchospasm. Some patients develop gastrointestinal symptoms (nausea, cramps, vomiting, and fecal incontinence). The blood pressure may collapse, either just due to a shift of volume into the extravascular space or due to cardiac arrhythmia. The full syndrome is anaphylactic shock, which is lethal in ~1% of cases. Risk factors for a severe episode are fulminant appearance, pre-existing (undertreated) asthma, and older age, as myocardial infarction or cerebral hypoxia/damage can lead to death days after the acute event. Anaphylaxis is a severe event, and survivors not infrequently have some cognitive or intellectual impairment. Table 48.1 summarizes the main drugs causing anaphylaxis.

Most IgE-mediated reactions to drugs are less severe, and often only urticaria, angioedema, or a local wheal may develop. However, *any IgE-mediated drug allergy can be potentially life threatening*, as the mild symptoms might be due to a relatively low dose, and each treatment may boost the IgE response.

PSEUDOALLERGY (NONIMMUNE-MEDIATED HYPERSENSITIVITY)

An unsolved problem are so-called ‘pseudoallergic’ reactions (*nonimmune-mediated hypersensitivities*), which in fact are as frequent as IgE-mediated reactions. The majority of these reactions imitate the clinical features of immediate reactions (erythema, urticaria) and are not dangerous, but some of these reactions cause anaphylaxis and can be lethal. They can appear at the first encounter with the drug and tend to arise less rapidly (often >15 minutes) than true IgE-mediated allergies; they require higher doses, and the typical initial symptoms for anaphylaxis, namely palmar and/or plantar itch, are less common. High serum tryptase levels after some reactions underline the role of mast cell degranulation at least in some of these reactions.

‘Pseudoallergic’ reactions can be elicited by many drugs, but some drugs seem to elicit them more often (Table 48.1). *In vitro*, these drugs do not release mediators from basophils or mast cells. Some people seem to be more prone to react in this way, and they develop similar, mostly mild symptoms to a quite heterogeneous range of drugs, with clearly distinct chemical and pharmacological features. Neither IgE nor T-cell reactions have been demonstrated, and only very few patients have

Table 48.1 Common causes of allergic and 'pseudoallergic' drug reactions

Drugs involved in IgE-mediated allergies ^a	Drugs causing "pseudoallergic" reactions ^a

^a Not complete; only main groups mentioned. IgE, immunoglobulin E; NSAID, nonsteroidal anti-inflammatory drug.	

KEY CONCEPTS

THE PHARMACOLOGICAL INTERACTION OF DRUGS WITH IMMUNE RECEPTORS (P-I) CONCEPT POSTULATES DIRECT INTERACTION OF DRUGS WITH T-CELL RECEPTORS (TCR)^{7,11}

- Fixed antigen-presenting cells, unable to process antigens, can still present the drug and stimulate specific T cells
- Many drug-specific T cells are only stimulated if the drug is constantly present. Washing the cells removes the drug, whereas covalently bound haptens are not washed away
- Drug-reactive T-cell clones react to the drug within seconds or minutes, long before metabolism and processing can take place
- Some T-cell reactivity to drugs can already be observed in the absence of antigen-presenting cells
- The p-i concept has been found to be relevant for such different drugs as sulfamethoxazole, lidocaine, mepivacaine, celecoxib, lamotrigine, carbamazepine and *p*-phenylendiamine, causing MPE, DiHS/DRESS, AGEP, TEN, and contact dermatitis
- AGEP, acute generalized exanthematous pustulosis; DiHS, drug-induced hypersensitivity syndrome; DRESS, drug rash with eosinophilia and systemic symptoms; MPE, maculopapular exanthem; TEN, toxic epidermal necrolysis.

constantly elevated tryptase levels as a sign of a mastocytosis. Some reactions can be suppressed by pretreatment with antihistamines.

IgG-mediated reactions (cytotoxic mechanism, type II)

Type II and type III reactions rely on the formation of complement-fixing IgG antibodies (IgG₁, IgG₃). Occasionally, IgM is involved. They are similar, as both depend on the formation of immune complexes and

interaction with complement and Fcγ receptor (FcγRI, IIa and IIIa) bearing cells (on macrophages, natural killer cells, granulocytes, platelets), but the target structures and physiological consequences are different.

In type II reactions, either the antibody is directed to cell structures on the membrane (rarely) or immune complex activation occurs on the cell surface. Both events can lead to cell destruction or sequestration. Affected target cells include erythrocytes, leukocytes, platelets, and probably hematopoietic precursor cells in the bone marrow. The mechanism of type II reaction is not as clear as originally thought, since a clear hapten-specific immune reaction can often not be documented.^{12, 13} One can distinguish two patterns:

1. Development of an IgG immune reaction to the hapten-carrier complex, mostly after longer duration of high-dose treatment. This is rather rare and best documented for high-dose penicillin and cephalosporin treatments. The immune reaction is due to complement-fixing antibodies (IgG₁, IgG₃, rarely IgM). Some antibody reactivity may be directed to the carrier molecule itself (i.e., autoantibodies). Onset of this autoimmune form is less abrupt, but it lasts longer (weeks instead of days) after cessation of the drug.
2. Nonspecific adherence with autoantibody induction can occur when a drug or metabolite becomes adsorbed to the erythrocyte or thrombocyte membrane, creating a new antigenic complex in combination with the cell membrane. For example, quinine-induced immune thrombocytopenia is caused by IgG and/or IgM immunoglobulins that react with selected epitopes on platelet membrane glycoproteins, usually GPIIb/IIIa (fibrinogen receptor) or GPIb/IX (von Willebrand factor receptor) only when the drug is present in its soluble form.¹² Well-documented cases are due to quinine, quinidine, or sulfonamides. The antibodies are clearly not hapten-specific, and it remains enigmatic how a soluble drug can promote binding of an otherwise innocuous antibody to a membrane glycoprotein and cause platelet destruction.

The antibody-coated cells will be sequestered to the reticuloendothelial system in liver and spleen by Fc- or complement receptor binding. More rarely, intravascular destruction may occur by complement-mediated lysis.

Fig. 48.2 Kinetic of immunoglobulin E (IgE) and T-cell-mediated reactions. (A) Schematic representation of a sensitization phase, which was asymptomatic. At re-exposure at a later time point symptoms appear rapidly, mostly within 1 hour. (B) Appearance of exanthem in gemifloxacin-treated healthy volunteers. The largest study undertaken to investigate drug-induced side effects was performed with gemifloxacin, a quinolone. Initial data revealed that rashes appeared more commonly in women under 40 years of age and in those patients submitted to longer treatment (> 7 days). A prospective study was performed in 987 healthy women aged 18–40; 790 (80%) were treated with gemifloxacin for 10 days while the remaining 197 (20%) received ciprofloxacin for 10 days. A mostly very mild exanthem appeared in 260/790 (31.7%) gemifloxacin-treated women but only in 7/197 (4.3%) ciprofloxacin-treated women, with a clear peak on days 8–10 after treatment onset. Aminopenicillin-induced exanthems have a similar time kinetic. Data from Food and Drug Administration website: http://www.fda.gov/ohrms/dockets/ac/03/slides/3931S1_04_LFLife%20Sciences-Factive.pdf.

Fig. 48.3 Clinical pictures and immunohistologies of various forms of drug-induced exanthem. Urticaria with itching wheals (nonsteroidal anti-inflammatory drug intolerance reaction).

Hemolytic anemia has been attributed to penicillin and its derivatives, cephalosporins, levodopa, methyl dopa, quinidine, and some anti-inflammatory drugs. Today cephalosporins are the main cause. The clinical symptoms of hemolytic anemia are insidious and may be restricted to symptoms of anemia (fatigue, paleness, shortness of breath, tachycardia) and jaundice with dark urine. Laboratory investigation may reveal reduced erythrocyte and hemoglobin levels, increased reticulocytes, and positive direct and (if the drug is present during the test) indirect Coombs tests. Unconjugated bilirubin levels are elevated and haptoglobin is decreased. Urinary hemoglobin and hemosiderin are increased.

Thrombocytopenia is a relatively common side effect of drug treatment. Acute, sometimes severe and life-threatening thrombocytopenia is a recognized complication of treatment with quinine, quinidine, sulfonamide antibiotics, and many other medications. It can also complicate treatment with biologicals, which often contain human Fc elements themselves. Drug-induced immune thrombocytopenia usually develops after 5–8 days of exposure to the sensitizing medication or after a single exposure in a patient exposed previously to the same drug. Patients often present with widespread petechial hemorrhages in the skin and buccal mucosa, sometimes accompanied by urinary tract or gastrointestinal

CLINICAL PEARL

IMMUNOGLOBULIN E (IgE)-MEDIATED
DRUG ALLERGIES

- >> Up to 50% of patients with IgE-induced anaphylaxis to certain drugs have no history of previous drug exposure!
- >> Anaphylaxis occurs rapidly (< 20 minutes), seldom later
- >> Asphyxia is probably the main cause of lethal anaphylaxis
- >> Cardiac arrest can be the sole symptom of an anaphylaxis (in particular during anesthesia)
- >> In certain cases desensitization procedures are possible and may allow reuse of the drug

bleeding. Intracranial hemorrhage is rare, but has been reported. After discontinuing the culprit medication, platelet counts usually return to normal within 3–5 days.

A special, intermediate form between type II and III reactions is *heparin-induced thrombocytopenia*: Platelets have low-affinity Fc-receptors (Fcγ-RIIIa) that can bind immune complexes, and activate platelets.¹⁴ Heparin is a high-molecular-weight, sulfated, linear polysaccharide that inhibits blood coagulation by activating regulatory proteins such as antithrombin III. About 50% of patients anti-coagulated with heparin for > 7 days produce antibodies that recognize complexes consisting of heparin and platelet factor 4, a CXC chemokine normally stored in platelet alpha granules. When a patient with such an antibody is given heparin, heparin–PF4 complexes are formed. These complexes react with antibodies to form immune complexes, which bind to the platelet FcIgG-RIIIa receptors, leading to platelet activation, additional PF4 release and eventually, platelet destruction. Thrombocytopenia occurs in about 5% of patients given heparin and is rarely severe enough to cause bleeding. However, about 10% of affected patients experience paradoxical thrombosis that can be life-threatening.

IgG-mediated reactions (immune complex
deposition, type III)

Immune complex formation is a common event during a normal immune response and does not normally cause symptoms. Immune complexes can also be formed during drug treatment, either if the drug forms a hapten-carrier complex and thus gives rise to an immune reaction or if the drug is a (partly) foreign protein that elicits an immune reaction itself (e.g., chimeric antibodies). Such immune complexes will normally be rapidly cleared, by binding to Fcγ-RI or CR1 on reticuloendothelial cells. No symptoms arise, but the efficiency of treatment decreases.

Why immune complex disease develops under certain circumstances is not clear. Very high immune complex levels, a relative deficiency of some complement components, and thus lower capacity to eliminate immune complexes or an aberrant Fcγ-R function might be responsible. Recently, a low copy number of Fcγ-RIII were found to be associated with another immune complex disease, glomerulonephritis.¹⁵

Type III reactions may present as small-vessel vasculitis and/or serum sickness: Serum sickness was first described with heterologous or foreign serum used for passive immunization. Antibodies are generated within

4–10 days, which react with the antigen, forming soluble circulating immune complexes. Complement (C1q)-containing immune complexes are deposited in the postcapillary venules and attract leukocytes by interacting with their Fcγ-RIII,¹⁶ which then release proteolytic enzymes that mediate tissue damage.

Currently, nonprotein drugs are the most common cause of serum sickness. Hypersensitivity vasculitis reportedly has an incidence of 10–30 cases per million people per year. Most reports concern cefaclor, followed by trimethoprim-sulfamethoxazole, cephalexin, amoxicillin, nonsteroidal anti-inflammatory drugs (NSAIDs), and diuretics.

The main symptoms of immune complex diseases are arthralgia, myalgia, fever, and vasculitis. This may be localized mainly to the skin as 'palpable purpura' – purplish, red spots, usually on the legs. In children, it is often diagnosed as Henoch–Schönlein purpura, often with arthritis. Lesions may coalesce to form plaques that occasionally ulcerate. The internal organs most commonly affected are the gastrointestinal tract, the kidneys, and joints. The prognosis is good when there is no internal involvement. Histology can reveal IgA-containing immune complexes, and the histology of kidney lesions is in fact identical to IgA nephropathy.

T-CELL-MEDIATED, DELAYED DRUG
HYPERSENSITIVITY REACTIONS

The original Gell and Coombs classification was established before a detailed analysis of T-cell subsets and functions was available. In the meantime immunological research has revealed that the three antibody-dependent types of reactions require the involvement of helper T cells. Moreover, T cells can orchestrate different forms of inflammation. Therefore T-cell-mediated type IV reactions have been further subclassified into IVa–IVd reactions, as shown in Figure 48.4.⁷ This subclassification considers the distinct cytokine production by T cells and thus incorporates the well-accepted Th1/Th2 distinction of T cells; it includes the cytotoxic activity of both CD4 and CD8 T cells (IVc); and it emphasizes the participation of different effector cells such as monocytes (IVa), eosinophils (IVb), or neutrophils (IVd), which cause the inflammation and tissue damage:

Type IVa reactions correspond to Th1-type immune reactions: Th1-type T cells activate macrophages by secreting large amounts of interferon-γ (IFN-γ), drive the production of complement-fixing antibody isotypes involved in type II and III reactions (IgG₁, IgG₃), and are co-stimulatory for proinflammatory responses (TNF, IL-12) and CD8 T-cell responses. The T cells promote these reactions by secretion of IFN-γ and possibly other cytokines (TNF-α, IL-18). An *in vivo* correlate would be monocyte activation, e.g., in skin tests to tuberculin or even granuloma formation, as seen in sarcoidosis. On the other hand, these Th1 cells are known to activate CD8 cells, which might explain the common combination of IVa and IVc reactions (e.g., in contact dermatitis).

Type IVb corresponds to the Th2-type immune response. Th2 T cells secrete the cytokines IL-4, IL13, and IL-5, which promote B-cell production of IgE and IgG₄, macrophage deactivation and mast cell and eosinophil responses. The high production of the Th2 cytokine IL-5 leads to eosinophilic inflammation, which is the characteristic inflammatory cell type in many drug hypersensitivity reactions.⁷ In addition, there is a link to type I reactions, as Th2 cells support IgE production by IL-4/IL-13 secretion. *In vivo* correlates include eosinophil-rich maculopapular exanthem (MPE), infestations with nematodes, or allergic inflammation of the bronchi or nasal mucosa (asthma and rhinitis).

	Type I	Type II	Type III	Type IV a	Type IV b	Type IV c	Type IV d
Immune reactant	IgE	IgG	IgG	IFN γ , TNF α (T $_H$ 1 cells)	IL-5, IL-4/IL-13 (T $_H$ 2 cells)	Perforin/ GranzymeB (CTL)	CXCL-8, GM-CSF (T-cells)
Antigen	Soluble antigen	Cell or matrix-associated antigen	Soluble antigen	Antigen presented by cells or direct T cell stimulation	Antigen presented by cells or direct T cell stimulation	Cell-associated antigen or direct T cell stimulation	Soluble antigen presented by cells or direct T cell stimulation
Effector	Mast-cell activation	FcR $^+$ cells (phagocytes, NK cells)	FcR $^+$ cells Complement	Macrophage activation	Eosinophils	T cells	Neutrophils
							
Example of hypersensitivity reaction	Anaphylaxis, allergic rhinitis, asthma (with IVb)	Haemolytic anaemia, thrombocytopenia	Serum sickness, Arthus reaction	Tuberculin reaction, contact dermatitis (with IVc)	Maculopapular exanthema with eosinophilia, Chronic asthma, allergic rhinitis	Contact dermatitis, maculopapular and bullous exanthem, hepatitis	AGEP, Behçet disease, psoriasis

Fig. 48.4 Revised Gell and Coombs classification of drug reactions. Drugs can elicit all types of immune reactions. Although all reactions are T-cell-regulated, the effector functions are either predominantly antibody-mediated (type I–III) or rely more on T-cell/cytokine-dependent functions (type IVa–IVd). Type I reactions are IgE-mediated. Cross-linking IgE molecules on high-affinity IgE receptors (Fc ϵ -RI) on mast cells and basophilic granulocytes leads to degranulation and release of mediators, which cause a variety of symptoms (vasodilatation, increased permeability, bronchoconstriction, itch). Type II reactions are IgG-mediated, and cause cell destruction due to complement activation or interaction with Fc γ receptor-bearing killer cells. Type III reactions are also IgG-mediated. Complement deposition and activation in small vessels and recruitment of neutrophilic granulocytes via Fc γ receptor interaction lead to a local vascular inflammation. Type IVa correspond to Th1 reactions with high IFN- γ /TNF- α secretion and involves monocyte/macrophage activation. Often, one can see also a CD8 cell recruitment (type IVc reaction). Type IVb reactions correspond to eosinophilic inflammation and to a Th2 response with high IL-4/IL-5/IL-13 secretion; they are often associated with an IgE-mediated type I reaction. Type IVc: the cytotoxic reactions rely on cytotoxic T cells (both CD4 and CD8 cells) themselves as effector cells. They seem to occur in all drug-related delayed hypersensitivity reactions. Type IVd reactions correspond to a T-cell-dependent, sterile neutrophilic inflammatory process. They are clearly distinct from the rapid influx of polymorphonuclear leukocytes in bacterial infections and seem to be related to high CXCL-8/granulocyte-macrophage colony-stimulating factor (GM-CSF) production by T cells (and tissue cells). The role of IL-17 in IVd reactions is not yet defined. (Modified from Pichler WJ. Immune mechanism of drug hypersensitivity. *Immunol Allergy Clin North Am* 2004; 24: 373–397, with permission from Elsevier.)

KEY CONCEPTS

IMMUNOLOGICAL FINDINGS IN DRUG-INDUCED EXANTHEMA

- >> Drug-specific T cells are found in the blood, in affected skin, and in positive patch tests
- >> Drug-specific T cells show a high frequency for many years after the reaction (1:250–1:3000 of CD4 T cells react with the drug)
- >> Both drug-specific CD4 and CD8 cells can kill in a drug-dependent manner. CD4-mediated killing is perforin/granzyme B-dependent and responsible for focal, hydropic degeneration of keratinocytes in maculopapular exanthem
- >> The clinical picture of the exanthem is determined by the cytokine released by the T cells infiltrating the skin. Secretion of interferon- γ \rightarrow macrophage activation; secretion of interleukin-5 \rightarrow eosinophil activation; secretion of CXCL-8 and granulocyte-macrophage colony-stimulating factor \rightarrow neutrophil activation and recruitment
- >> A high number of drug-specific CD8 T cells causes more severe, bullous skin diseases, probably because all cells are targets for CD8-mediated cytotoxicity
- >> CD8-mediated severe reactions to carbamazepine, allopurinol, and abacavir show striking human leukocyte antigen (HLA)-B associations, which differ with different drugs

Type IVc

T cells can also act as effector cells: they emigrate to the tissue and can kill tissue cells like hepatocytes or keratinocytes in a perforin/granzymeB and FasL-dependent manner (Fig. 48.5).^{17, 18} Such reactions occur in most drug-induced delayed hypersensitivity reactions, mostly together with other type IV reactions (monocyte, eosinophil, or polymorphonuclear leukocyte recruitment and activation). Cytotoxic T cells thus play a role in maculopapular or bullous skin diseases as well as neutrophilic inflammation, such as acute generalized exanthematous pustulosis (AGEP), and in contact dermatitis. Type IVc reactions appear to be dominant in bullous skin reactions like Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN), where activated CD8 T cells kill keratinocytes,^{7, 17, 18} but may also be dominant in drug-induced hepatitis or nephritis.

Type IVd

Another, rather neglected possibility is that T cells can coordinate sterile neutrophilic inflammation. A typical example would be AGEP. In this disease CXCL8 and granulocyte-macrophage colony-stimulating factor (GM-CSF)-producing T cells recruit neutrophilic leukocytes via CXCL8 release, and prevent their apoptosis via GM-CSF release.¹⁹ Besides AGEP, such T-cell reactions are also found in Behçet's disease and pustular psoriasis.²⁰

Tolerance mechanism

Most patients can take drugs without developing immune-mediated side effects. This could be because they lack precursor cells able to interact with the drug. But the great heterogeneity of the immune response to

drugs,⁷ a high precursor frequency in sensitized patients²¹ and the finding that 2–4% of the normal population, but 30% to >50% of HIV-infected patients, may react with sulfamethoxazole suggests that it is not a lack of precursor cells but other factors like the underlying immune status (preactivation of memory T cells) and “regulatory” mechanisms that may be important. Thus “regulation” may occur on different levels and may be different for drugs stimulating the immune system via hapten and the p-i concept (see above).

Maculopapular exanthem (MPE)

The most frequent manifestations of drug allergies are delayed-appearing *cutaneous reactions* – so-called ‘rashes.’ They comprise a broad spectrum of clinical and distinct histopathological features which appear >6 hours to 10 days after drug intake (Fig. 48.2).

In all forms of delayed drug-induced reactions like exanthems, nephritis, and probably hepatitis, cytotoxic mechanisms seem to play an important role. The clinical picture is determined by the strength of cytotoxicity (amount of drug-specific cytotoxic T cells and tissue destruction), the generation of cytotoxic CD8 versus CD4 cells, and the type of associated effector mechanism (monocyte or activation of eosinophils and neutrophilic granulocytes).

MPE is the most frequent drug hypersensitivity reaction, affecting 2–8% of hospitalized patients, especially after treatment with β -lactams, sulfamethoxazole, quinolones, diuretics, and many more.^{4, 5} In most cases it appears 8–11 days after start of treatment (Fig. 48.2), but sometimes even 1–2 days after stopping treatment (Fig. 48.6). In previously sensitized individuals it can appear on the first day of treatment. It is clearly dose-dependent. A study investigating exanthem after treatment with the quinolone gemifloxacin showed that females of childbearing age had a higher risk of exanthem, suggesting an influence of estrogens on the clinical manifestation (Fig. 48.2B) (http://www.fda.gov/ohrms/dockets/ac/03/slides/3931S1_04_LFLife%20Sciences-Factive.pdf). Most MPE, particularly if caused by β -lactams or gemifloxacin, are rather mild, and treatment with an emollient cream, and possibly topical corticosteroids, or systemic antihistamines to treat pruritus is sufficient. Some patients can continue treatment without aggravation. The exanthem often heals with desquamation within 2–10 days after stopping the incriminated drug. It is unlikely that SJS/TEN will develop from MPE, as the cells involved are different. On the other hand, some drugs may induce a mixed CD4 and CD8 cell activation (Table 48.2). In such cases prolonged treatment may lead to confluence of the papules, the patient may complain of malaise and fever, and liver function tests indicate hepatitis (more than threefold increased transaminases). Eosinophilia (> 0.5 g/l) and activated CD8 cells are found in the blood.²² This illustrates that even “mild” drug hypersensitivity reactions are *systemic diseases*, and that cutaneous manifestations may only be the tip of the iceberg.

Immunohistology revealed drug-specific CD4⁺ cell infiltration (CLA⁺, CCR6⁺) in perivascular areas of the dermis.^{7, 22} Some T cells progress into the dermoepidermal junction zone and epidermis, where they are reactivated (MHC class II⁺ and CD25⁺) and kill keratinocytes in a contact-dependent way by releasing perforin/granzyme B. Some keratinocytes undergo hydropic degeneration, but this apoptosis is not as extensive as with CD8 T-cell-mediated killing (Fig. 48.5). In addition, the immigrating CD4 T cells exhibit a heterogeneous cytokine profile, including type 1 (IFN- γ) and type 2 (IL-4, IL-5) cytokines, suggesting

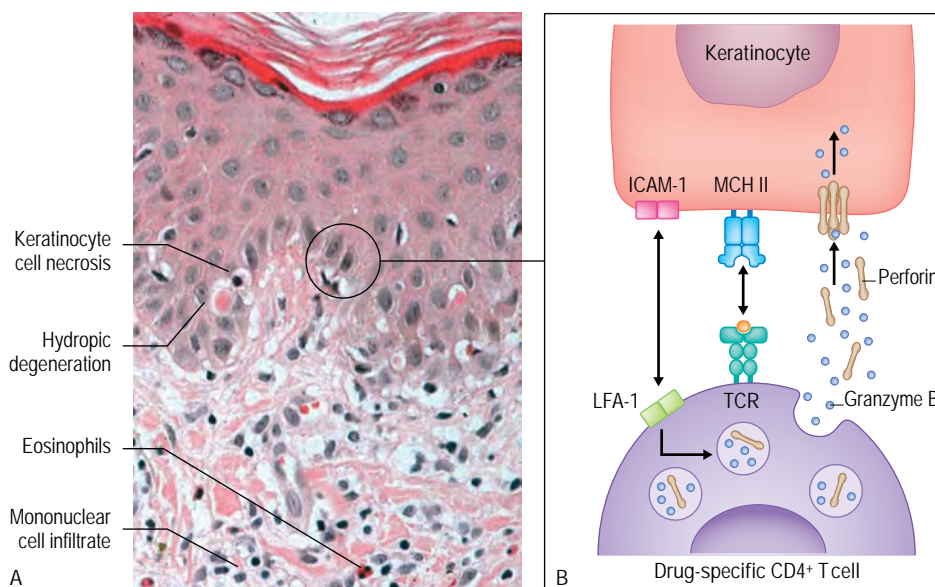

Fig. 48.5 (A) Typical histology of a maculopapular exanthem. Note the focal keratinocyte necrosis, often in close apposition of T cells (which have cytotoxic potential and are perforin-positive). (B) Schematic representation of CD4-mediated killing of activated keratinocytes, which express major histocompatibility complex (MHC) class II and ICAM1 molecules. (Modified from Pichler WJ. Delayed drug hypersensitivity reactions. *Ann Intern Med* 2003; 139: 683–693, with permission from the American College of Physicians.)

that both Th1 and Th2 cells infiltrate the skin. The cytokine IL-5 is also detectable in the serum. Tissue and blood eosinophilia can be found.^{22–24} The recruitment of eosinophils is also enhanced by expression of the chemokines eotaxin and RANTES in MPE-lesions.

Acute generalized exanthematous pustulosis

Acute generalized exanthematous pustulosis is a rare disease (~ 1:100 000 treatments) with an estimated incidence equal to severe bullous skin diseases (SJS and TEN combined).^{19,25} It is caused by drugs in > 90% of cases (Table 48.2). Its clinical hallmark is the rapid appearance of myriads of disseminated, *sterile* pustules in the skin (Fig. 48.7), often 3–5 days after starting treatment. Patients have fever and massive leukocytosis in the blood, sometimes with eosinophilia, but no involvement of mucous membranes. Epicutaneous patch test reactions can cause a similar pustular reaction locally (Fig. 48.7).

Immunohistology of the acute lesion reveals subcorneal or intraepidermal pustules, which are filled with neutrophilic granulocytes and surrounded by activated, HLA-DR-expressing CD4 and CD8 T cells. Keratinocytes show elevated expression of the neutrophil-attracting chemokine IL-8 (CXCL-8), and even the T cells migrating into the epidermis express CXCL-8 and GM-CSF. Analysis of sequential patch test reactions at 48–96 hours suggests that drug-specific cytotoxic T cells emigrate first, causing formation of vesicles by killing keratinocytes. Subsequently T cells and keratinocytes release CXCL8, which recruits granulocytes into the vesicles that then transform into pustules.¹⁹ Some pustules coalesce together and can form bullae. The condition is fatal in 2–4% of cases, particularly in older people. Healing occurs within 5 days after stopping the drug. This disease and the underlying T-cell reaction

seem to be a model for sterile neutrophilic inflammations (type IVd) like pustular psoriasis and Behçet's disease.²⁰

Bullous exanthems, Stevens–Johnson syndrome, and toxic epidermal necrolysis

The most severe forms of drug-induced skin reactions involve formation of bullae. The most severe bullous skin reactions are SJS and TEN. TEN and SJS are rare (~1:1 000 000 for TEN, ~1:100 000 for SJS). They are today considered to be the milder and more severe form of the same disease (SJS < 10% skin detachment, TEN > 30% detachment). They are graded according to SCORTEN, whereby age, underlying disease and the amount of maximal skin detachment are the most important prognostic factors. According to the European study group of severe cutaneous drug reactions, SJS has a mortality of ~13%, and TEN of ~39%. The intermediate form with 10–30% skin detachment is called SJS/TEN overlap syndrome and has a lethality of ~21%.

SJS/TEN are clearly different from erythema exudativum multiforme, which is mainly caused by viral infections,³ is often recurrent, and affects younger persons (mean age 24 years). In ~6% no drug treatment was given the week before SJS/TEN started and an infectious origin (*Mycoplasma pneumoniae*, *Klebsiella pneumoniae*) was suspected. It can also be due to graft-versus-host disease. Most reactions start within the first 8 weeks of treatment (mean onset of symptoms at about 17 days), with some differences according to the causing drug (e.g., it may appear later with sulfonamide antibiotics).

SJS/TEN can develop quite rapidly. Initially a macular, purple-red exanthem can often be observed, which can become painful – an ominous sign. Within 12–24 hours bullae may be seen, and the Nikolsky

Fig. 48.6 Clinical pictures and immunohistologies of various forms of drug-induced exanthem. Maculopapular drug eruption (**C**): the immunohistology reveals infiltration of CD4 (**A**) and only a few CD8 T cells (**B**) in the dermis and epidermis. These cells express perforin and granzyme B and, to a variable degree, FasL. (From Hari Y, Frutig-Schnyder K, Hunni M, et al. T cell involvement in cutaneous drug eruptions. *Clin Exp Allergy* 2001; 31: 1398–1408, with permission from Blackwell Publishing.)

sign is positive (Table 48.3). Stopping drug treatment at this stage may not prevent SJS developing, but might prevent an even more severe reaction (TEN). Mucous membranes (mouth, genitalia) are involved with blister formation, as well as a purulent keratoconjunctivitis with formation of synechiae, which may result in permanent eye damage.

The main causes for SJS/TEN are drugs (Table 48.2), which might differ in frequency in various regions due to genetic and ethnic background. Important risk factors are HIV infection (low CD4, high CD8 counts), renal diseases, and active systemic autoimmune diseases such as systemic lupus erythematosus, Still's syndrome, Sjögren's disease, and rheumatoid arthritis. In histology of toxic epidermal necrolysis, many dead keratinocytes are found, but cell infiltration is scarce. However, the bullae may be filled by cytotoxic CD8 T cells, expressing CD56 and $\alpha\beta$ -TCRs, which kill via perforin/granzyme B but not via the Fas-mediated pathway at this stage of the disease.¹⁷ On the other hand, the massive cell

death of keratinocytes is hard to reconcile with a cell contact-dependent killing process. It has been proposed that the apoptosis of keratinocytes is due to FasL, a soluble molecule of the TNF family, which binds to keratinocytes via Fas and functions as a so-called death receptor.²⁶ Since blocking anti-Fas antibodies are found in immunoglobulin preparations, it has been proposed to treat patients with TEN with immunoglobulins, but the efficacy of this therapy is unproven.²⁷

Extensive research has not revealed a pharmacogenetic predisposition or low glutathione levels in affected persons. However, recent data have revealed striking HLA associations of severe, CD8-mediated drug hypersensitivity reactions.^{28–30} Three factors play a role: (1) the type of drug; (2) the type of reaction, as it was found for cytotoxic CD8 reactions only; and (3) possibly race, as some reactions were mainly described in Han Chinese. The HLA-B allele, which is the most polymorphic HLA allele, seems to be involved. In carbamazepine-induced SJS/TEN it is

Table 48.2 Drugs eliciting severe cutaneous or systemic reactions^a

Aminopenicillins^a	Nevirapine	Carbamazepine^b
Cephalosporins	Allopurinol	Phenytoin
Pristinamycin	Phenytoin^b	Lamotrigine
Celecoxib	Carbamazepine^b	Minocycline
Quinolone	Lamotrigine	Allopurinol ^b
Diltiazem	Co-trimoxazole	Dapsone
Terbinafine	Barbiturate	Sulfasalazine
Macrolides	Nonsteroidal anti-inflammatory drug (oxicams)	Co-trimoxazole (abacavir) ^c

^aList incomplete: the most frequent elicitors are given in bold.

^bThe type of reaction might be determined by the presence of a certain human leukocyte antigen (HLA)-B phenotype.

^cAbacavir-induced systemic reactions often lack eosinophilia and preferentially affect the respiratory and gastrointestinal tract.

HLA-B*1502; for phenytoin HLA-B*5601; and for abacavir HLA-B*5701 together with hsp70. It seems that in these CD8 T-cell reactions the HLA-B alleles favor the presentation of certain peptides capable of optimally presenting the drug/hapten. Alternatively, if the stimulation occurred via the p-i concept, certain MHC molecules might supplement the T-cell stimulation better than others, while absence of the allelic product renders the T-cell unresponsive to drug binding.

The extremely high association of certain HLA-B alleles and hypersensitivity reactions to certain drugs may be used to prevent such side effects in the future, as HLA-typing may identify patients at risk. Studies to determine the benefit of such predictive testing are under way.

Systemic drug reactions – severe drug hypersensitivity syndromes

Some drugs are known to cause a severe systemic disease, with fever, lymph node swelling, massive hepatitis, and various forms of exanthems (Table 48.2). A few patients develop colitis, pancreatitis, or interstitial lung disease.³¹ Over 70% have a marked eosinophilia (often $> 10^{12}/l$), and activated lymphocytes are often found in the circulation, similar to acute HIV or generalized herpes virus infections. This syndrome has many names. The most frequently used are drug (induced) hypersensitivity syndrome (DHS or DiHS) or drug rash with eosinophilia and systemic symptoms (DRESS). Importantly, the symptoms can start up to 12 weeks after starting treatment, often after increasing the dose, and may also persist and recur for many weeks, even after cessation of drug treatment. The clinical picture resembles a generalized viral infection, e.g., acute Epstein–Barr virus infection, but it is distinguished by the prominent eosinophilia. Many patients have facial swelling, and some have signs of a capillary leak syndrome, like patients having a cytokine release syndrome. Indeed, various cytokines are massively increased in the serum of these patients. As the clinical picture is quite dramatic and as the disease tends to persist in spite of stopping drug treatment, many patients *are not diagnosed correctly or in a timely manner*. However, physicians using anticonvulsants should be familiar with this syndrome, as it might occur in 1:3000 treated

patients. The mortality is ~10%, and some patients require emergency liver transplantation.

Patients with DiHS/DRESS have many activated T cells in the circulation. These drug-specific T cells are stimulated by the parent compound (p-i concept) and they secrete high amounts of IL-5 and IFN- γ .³² A peculiar feature of this syndrome is its long-lasting clinical course despite withdrawal of the causative drug. There may also be persistent intolerance to other, chemically distinct drugs, leading to flare-up reactions to a rather innocuous drug (e.g., acetaminophen) months after stopping the initial drug therapy, further adding to the confusion. Treatment often includes high doses of corticosteroids, particularly if the hepatitis is severe.

Recently, it has been shown that in many patients with this syndrome, human herpes virus 6 DNA can be found during the 3rd or 4th week of the disease (but not before), followed by a rising antibody titer to human herpes virus 6.³³ Other reports document reactivation of cytomegalovirus infection. Thus, similar to HIV, where T-cell activation can also enhance virus production, the drug-induced massive immune stimulation may somehow reactivate these latent lymphotropic herpes viruses, which subsequently replicate and possibly contribute to the chronic course and persistent drug intolerance in affected patients.

Many drugs can induce isolated hepatitis and some (penicillins, proton pump inhibitors, quinolones, disulfiram) can cause an isolated (interstitial) nephritis. More rare are interstitial lung diseases (furadantin), pancreatitis, isolated fever, or eosinophilia as the only symptom of a drug allergy. In drug-induced interstitial nephritis eosinophils can sometimes be detected in the urine (even in the absence of blood eosinophilia).

Multiple drug hypersensitivity syndrome

The term ‘multiple drug hypersensitivity’ is used to describe different forms of side effects to multiple drugs. Some physicians use the term to characterize patients with multiple drug intolerance (“pseudoallergy” to NSAID), others reserve this term for well-documented repeated immune-mediated reactions to structurally unrelated drugs.³⁴ Cross-reactivity due to structural similarity is excluded from the definition.

Fig. 48.7 Clinical pictures and immunohistologies of various forms of drug-induced exanthem. **(A)** Pustular drug eruption (acute generalized exanthematous pustulosis: AGEP). **(B)** Note the intraepidermal, nonfollicular pustules; **(C)** a patch test reaction leading to a pustular reaction is shown as well. (From Schaerli P, Britschgi M, Keller M, et al. Characterization of human T cells that regulate neutrophilic skin inflammation. *J Immunol* 2004; 173: 2151–2158. Copyright 2004, with permission from The American Association of Immunologists, Inc.)

In our experience, about 10% of patients with well-documented drug hypersensitivity (skin and/or lymphocyte transformation test positive) have multiple drug allergies.³⁵ For example, they may have reacted to injected lidocaine with angioedema and years later they develop contact allergy to corticosteroids. Alternatively, a patient reacts to amoxicillin, phenytoin, and sulfamethoxazole within a few months, but with different symptoms (MPE, DiHS/DRESS, erythroderma). Most of these patients have had rather severe reactions to at least one drug. An IgE-mediated reaction might be followed by a T-cell-mediated reaction. The pathophysiologic mechanism of this syndrome is unknown.

One explanation might be a deficient tolerance mechanism to small chemical compounds/xenobiotics. An immune reaction to a drug, whether via hapten or p-i mechanism, can be seen as a failure of tolerance, and the same patient might be prone to develop not only other drug allergies but also autoimmunity. Preliminary data suggest that previous drug allergy might be a risk factor for the development of delayed hypersensitivity reactions to radiocontrast media.

Multiple drug hypersensitivity should be differentiated from *flare-up reactions*. In patients with systemic drug allergies, the T-cell immune system is massively activated, similar to acute viral infections. As in the latter, these patients seem to have a higher tendency to react to a new drug and might show a flare-up of their rash to a new antibiotic, but the second drug remains negative in skin tests and is later well tolerated, if the co-stimulatory conditions are no longer present.

■ DIAGNOSIS OF DRUG HYPERSENSITIVITY ■

The diagnosis of drug hypersensitivity addresses three questions: (1) is it a drug hypersensitivity? (2) which mechanism might be involved? and (3) which drug has caused it? The symptoms can be extremely heterogeneous, and in a patient with ‘bizarre’ symptoms a drug hypersensitivity reaction should always be included in the differential diagnosis! On the other hand, some of the above-described skin exanthems are rather typical for drug hypersensitivity and easy to recognize.

CLINICAL DIAGNOSIS

Drug hypersensitivity is often suspected if a ‘rash’ appears. Differential diagnosis of this rash includes viral exanthems, occasionally other infections, food allergy, and a graft-versus-host reaction. Pruritus, blood eosinophilia, and recent administration of a new drug argue for an allergic reaction.

It is important to document the severity of the presumed drug hypersensitivity, as this may determine whether the drug can be given again. Special attention should be paid to the type and extent of skin symptoms, the involvement of mucosal areas, lymph node enlargement, fever, and subjective symptoms like malaise, as this could indicate involvement of internal organs. A painful skin and a positive Nikolsky sign might herald a severe bullous skin reaction, which can develop within hours. One should be aware of danger signs (Table 48.3) and the most important elicitors of SJS/TEN and DRESS (Table 48.2). Some patients have no skin involvement, but develop an isolated drug-allergic hepatitis or interstitial nephritis.

Different mechanisms can lead to drug hypersensitivity symptoms. They should be differentiated, as they need distinct diagnostic steps and may have a different prognosis; the combination of symptoms and time course usually helps to discriminate them. Immediate reactions start < 1

Fig. 48.8 Clinical pictures and immunohistologies of various forms of drug-induced exanthem. Maculopapular drug eruption (A) with some blisters exhibiting more CD8 T cells by immunohistology (C). Table 48.3 Clinical and laboratory investigations and *danger signs*^a in drug-induced exanthems

Clinic	Laboratory
Extent and type of exanthem (infiltration, <i>bullae</i> , <i>pustules</i>)	Eosinophilia (> 1000–1200/ μ l ^b); <i>atypical (activated) lymphocytes in the circulation</i> (> 2% ^b)
Pain of skin, <i>Nikolsky sign</i>	
Involvement of mucous membranes	C-reactive protein elevation
Systemic symptoms (<i>malaise</i> , <i>fever</i>)	Liver enzymes (ALAT, ASAT, γ GT, AP) (increase >2–3 \times ^b) additional investigations depend on clinical signs, liver, kidney, lung, pancreas involvement (urine analysis, creatinine)
Lymphadenopathy, <i>hepatosplenomegaly</i>	

^aDanger signs *in italics*.

^bThe cut-off values of the laboratory parameters are estimates, and are not based on prospective studies; severe reactions can also develop in the absence of these signs!

THERAPEUTIC PRINCIPLES

CROSS-REACTIVITY

- >> The risk of cross-reactivity depends on the type of reaction
- >> In nonsteroidal anti-inflammatory drug-induced 'pseudoallergy,' cross-reactivity seems to be due to the pharmacological action and not the structure
- >> Immunoglobulin E (IgE)-mediated reactions have a higher degree of cross-reactivity than T-cell reactions, probably because antibodies can recognize small molecular components, whereas T cells tend to recognize the complete structure
- >> Cross-reactivity of T cell and antibodies is common within the same class of drugs (e.g., penicillins, quinolones, pyrazolones, cephalosporins)
- >> **Penicillin–cephalosporin cross-reactivity**
- >> Not seen in T-cell-mediated reactions (maculopapular exanthem); in IgE-mediated reactions cross-reactivity might occur in ~4% of penicillin skin test-positive patients with first- and second-generation cephalosporins. The chance of cross-reactivity is very low if the second drug is negative in skin tests
- >> **Sulfonamide cross-reactivity**
- >> There is an extensive cross-reactivity between sulfonamide-containing antibacterials (sulfanilamides), which mainly induce sensitization, but not with other drugs containing a sulfonamide (e.g., furosemide, celecoxib, glibenclamide)

hour after drug intake and are usually IgE-mediated (or due to drug-induced mast-cell release). Occasionally, IgE-mediated reactions occur later than 1 hour. Typical symptoms are urticaria and anaphylaxis. Delayed reactions start > 12 hours after drug intake and are mostly non-IgE-mediated, but involve T-cell orchestrated inflammation or IgG-mediated reactions. In highly sensitized individuals symptoms can arise as early as 2–4 hours after drug intake – the more drug-specific precursor T cells are present, the more rapidly symptoms may appear.

Laboratory investigations can also help to determine the severity of the reaction. In more severe acute reactions tryptase levels should be determined, optimally between 2 and 4 hours after the peak of the reaction to confirm mast cell involvement. The analysis should be repeated later (> 2 days) to rule out a constitutively elevated tryptase level (mastocytosis). Such measurements are particularly important if anaphylaxis is suspected during anesthesia, where the sole sign of anaphylaxis might be cardiac arrest, without skin symptoms.

In delayed reactions a differential blood count may reveal activated lymphocytes and eosinophilia, which is common in drug hypersensitivity (observed in up to ~40% of patients with MPE, in 30% with AGEP (together with leukocytosis, and in > 70% in DiHS/DRESS). Measurements of liver enzymes (ALAT, ASAT, ALP, and γ GT) should be done in patients with malaise, in those with extensive skin involvement, or if drugs known to cause DiHS/DRESS or hepatitis/cholestasis are involved. A transient mild hepatitis is not rare and seems to occur in ~25% of patients with more severe MPE.²² Dependent on the symptoms

other tests may also be indicated (creatinine, urinary analysis). C-reactive protein (CRP) may be elevated (e.g., in drug-induced interstitial lung or kidney diseases), but can be normal even in severe hypersensitivity reactions like DiHS/DRESS.

IDENTIFYING THE CULPRIT DRUG

The important questions are: which drugs were taken, and since when? Was the dose increased? Are there co-medications? and could they possibly interfere with drug metabolism? How were the drugs tolerated previously? Were other drugs tolerated that are known to cause similar effects? What was the underlying disease? Have similar reactions already occurred previously without or with drugs? Books listing side effects, websites (e.g., www.pneumotox.com) and pharmaceutical companies can provide information about the known side effects of a drug. In many instances, the history and these sources may allow a rather conclusive allocation of symptoms and drug intake. However, many patients have taken several drugs and the history alone may be insufficient. In these cases further tests can be justified, although these are often not well validated.

The *in vivo* (skin test) and *in vitro* tests for drug allergy diagnosis are difficult to standardize. Although drug allergy is common it only occurs rarely for each individual drug; a single drug might elicit different types of symptom, requiring different tests; provocation tests – which would prove the allergy and the sensitivity of the test – are often not performed for ethical reasons, and for some tests living cells are needed rather than serum, which requires a great logistic effort. In spite of these obstacles, many groups perform tests, but two rules are important: (1) the test can only supplement the history; and (2) the sensitivity of the tests is generally low, thus a positive test may be more meaningful than a negative test, which cannot rule out a drug allergy.

For immediate reactions both prick and intradermal tests are available. Penicillin tests are widely used. To form repetitive determinants able to cross-link two Fc ϵ RI-bound IgE molecules, the drug is coupled to polylysine, either by opening the penicillin-ring and forming penicilloyl-carriers, or by binding via the thiol structure (minor components). The pure substance (e.g., amoxicillin) can also be evaluated, since it frequently gives positive skin tests as well. The sensitivity of these tests is controversial: older studies from the USA suggested a sensitivity of > 95%; but more recent studies from Spain found only 70%.³⁶ Other drugs can be tested as well by prick or intradermal tests, but false-positive reactions (e.g., to quinolones) can occur and it is essential to test control individuals as well. Further information on test procedures and concentrations is available elsewhere.³⁷

In vitro tests for immediate reactions include the determination of specific IgE. However, the sensitivity of commercial assays for drug-specific IgE appears to be rather low, while published "in-house" tests have been reported to help in the diagnosis and discrimination from pseudoallergic reactions.^{6, 7} Various read-out systems for basophil degranulation/activation tests have been proposed to be usable for drug hypersensitivity diagnosis (e.g., Flow-Cast). Sensitivity in IgE-mediated reactions is reported to be ~40%, and in "pseudoallergic" reactions to NSAIDs up to 70%.³⁸

In Europe it is common to perform patch tests for delayed reactions (e.g., for contact dermatitis).³⁹ The overall sensitivity is considered to be < 50%³⁹ and depends on the disease (often negative in macular reactions, and delayed urticarial exanthems, but more useful in severe MPE, DiHS/DRESS, AGEP: Fig. 48.7). This is a reliable test for abacavir hypersensitivity, even if only hepatitis occurs.

THERAPEUTIC PRINCIPLES

TREATMENT

- >> Stop drug(s)
- >> Avoid drugs, until culprit drug is identified
- >> Avoid re-exposure to the drug class (cross-reactivity) in acute immunoglobulin E-mediated reactions, in acute "pseudoallergic" reactions, and in severe delayed reactions
- >> Symptomatic treatment according to symptoms
- >> Avoid treating through with drugs known to cause toxic epidermal necrolysis, drug-induced hypersensitivity syndrome or drug rash with eosinophilia and systemic symptoms, or if danger signs are present

The lymphocyte transformation (proliferation/activation) test (LTT) relies on the activation and proliferation of T cells cultured in the presence of the drug.⁴⁰ Reactivity can be measured by ³H-thymidine incorporation after 5–6-day culture, or by ELISPOT, CSFE staining, CD69 upregulation. LTT is cumbersome, but a clearly positive value is useful. The sensitivity of LTT depends on the pathophysiologic mechanism of the drug hypersensitivity and is > 90% for DiHS/DRESS, but lower in more cytotoxic reactions like SJS/TEN. LTT is positive in drugs sensitizing via the hapten mechanism or stimulated via the p-i concept.

Provocation tests are considered to be the gold standard for the diagnosis. They are useful for immediate reactions, but less so for delayed reactions.⁴¹ Cofactors are often important, which are absent during provocation, and the dose to elicit symptoms will often not be reached. Thus one might be able to exclude immediate reactions to the dose used in the provocation test, but treatment with higher doses might still cause symptoms.

THERAPEUTIC ASPECTS

The therapy of drug hypersensitivity diseases is dependent on the symptoms and ranges from the usual treatment of anaphylaxis to acute liver transplantation. Stopping the possible culprit drugs and avoiding them until clarity is achieved should be possible in most circumstances and might reduce the development of more severe symptoms. In some milder skin reactions, (e.g., nonbullous exanthem due to sulfamethoxazole in HIV-positive patients), experience has shown that continuation of treatment may be possible, whereas reintroducing the drug after stopping it may actually precipitate more severe symptoms.

DESENSITIZATION

Under certain circumstances a drug that causes allergic or 'pseudoallergic' side effects is essential for treatment, for example, penicillin to treat syphilis during pregnancy or certain cytostatic drugs in cancer treatments (e.g. cisplatin). Most desensitization protocols refer to hypersensitivity reactions involving mast cell degranulation, and the procedure is best established for penicillin and NSAIDs.⁴²

The starting dose for desensitization is determined by the dose the patient tolerated in skin testing. This dose generally translates to 1:10 000 of the therapeutic dose. Doubling doses are administered every 15 minutes until the full dose is reached. Once desensitization is completed, the patient can receive the full therapeutic course of penicillin via the desired route. If treatment is discontinued for more than 48 hours, the patient will once more be at risk to develop anaphylaxis and the full desensitization protocol must be repeated.

In dubious, skin test-negative cases, where one actually expects *no* allergy, *graded drug challenges* under careful supervision might be used starting with ~1/100 or 1/20 of the dose, and increasing the dose stepwise (double or triple) every 30–60 minutes. The full dose may be achieved in 1 day and can be continued during the next days.

Occupational and environmental allergic disorders

Emil J. Bardana Jr., Anthony Montanaro

49

The respiratory tract is second only to the skin as the most frequently impacted organ in the workplace. The upper and lower airways are the initial point of entry for a variety of ambient dusts, gases, fumes, and vapors. When relatively low concentrations of mild irritants are encountered, transient annoyance reactions may occur in exposed workers. Increasing concentrations of soluble inhalants may irritate the mucous membranes of the upper airways. Alternatively, soluble corrosive gases may cause skin burns, ocular damage, and acute inflammation in the nasopharynx, larynx, and lower airways. Other agents may not be directly damaging, but can induce sensitization, with subsequent onset of occupational asthma (OA). To date, approximately 300 industrial agents have been implicated in the induction of OA in susceptible individuals.

DEFINITION

OA is characterized by variable airway obstruction associated with bronchial hyperresponsiveness (BHR). It is caused by inflammation of the airways secondary to inhalation of dusts, gases, fumes, or vapors that are produced at, or incidentally present at, the workplace.¹ Bronchoconstriction caused by exercise or cold air is not sufficient to diagnose OA. The definition of OA assumes variable legal importance in the context of different workers' compensation statutes.² Pre-existing asthma does not preclude development of a work-induced respiratory disorder. In this instance, the clinician must determine whether the suspected work exposure caused the pre-existing asthma to become transiently symptomatic, or caused a permanent worsening of the pre-existing asthma by virtue of either an intense corrosive effect on the airways, or caused the development of a unique sensitization that amplified the pre-existing disease.

There are two main variants of OA based on pathogenesis. The most common type is immunologic OA which is caused by high-molecular-weight (HMW) proteins, glycoproteins, or polysaccharides derived from natural sources (animals, plants, foods, and enzymes) via an immunoglobulin E (IgE)-mediated response after a latent period of exposure (Table 49.1). Selected low-molecular-weight (LMW) agents are also capable of acting as haptens combining with human proteins to induce OA by an immunologic mechanism. A less common nonallergic variant, reactive air-

CLINICAL PEARLS

PATTERNS OF EXPOSURE IN OCCUPATIONAL ASTHMA

The key determinants of tissue damage from an inhaled agent are concentration, chemical reactivity, solubility, and duration of exposure

Host factors such as pre-existing disease and cigarette smoking also play a role

Highly soluble corrosive gases or fumes produce skin irritation or burns, ocular damage, erythema and swelling of the nose, and laryngeal swelling with cough

Relatively insoluble gases are more likely to penetrate deep into the lower airways with induction of chemical bronchitis, bronchiolitis, and alveolitis; corrosive damage to the skin and mucous membranes is not usual

The extent of exposure to a soluble gas can be determined by careful examination of the facial skin, eyes, nose, and pharynx

ways dysfunction syndrome (RADS) occurs after an acute exposure to a corrosive chemical, usually soluble in water, without a latent period. Agents known to cause OA have been classified in different ways, i.e., LMW versus HMW (Table 49.1), or immunogenic versus nonimmunogenic. They have also been classified according to their biochemical nature (e.g., plastics, chemicals, wood/vegetable dusts, pharmacologic agents) (Table 49.2).

The inhalational consequences of any industrial exposure is dependent on the physicochemical properties of the dust, gas, fume, or vapor involved, its concentration and duration of exposure, as well as specific host factors (Figs 49.1 and 49.2). There is significant variability of response from person to person even when the same concentration is encountered. Some industrial irritants are capable of causing tissue damage on direct contact. The extent of acute injury induced by irritant gases and vapors is highly dependent on their water solubility. Inhalation of highly soluble gases such as ammonia, sulfur dioxide, formaldehyde, or methyl isocyanate is likely to result in

Table 49.1 Classification of selected asthmagenic agents by molecular weight

Low-molecular-weight	High-molecular-weight
Acid anhydrides	Latex constituents
Diisocyanates	Insect parts
Reactive azo-dyes	Acarid emanations
Colophony (abietic acid, pimaric acid)	Animal protein
Epoxy amine compounds	Vegetable gums
Complex salts of platinum	<i>Bacillus subtilis</i> (alcalase)
Western red cedar (plicatic acid)	Hog trypsin
Ammonium persulfate	Papain
Penicillin	Castor bean dust
Cephalosporins	Green coffee bean dust
Spiromycin	Flour
Formaldehyde	Egg powder
Freon	Tobacco leaf
Vanadium	Silkworm larva

nasopharyngeal and laryngeal inflammation associated with erythema and edema. Such exposures can also induce irritant-related contact dermatitis of the exposed skin, as well as ocular irritation. Dependent on the concentration and duration of such exposures, the most significant pathology will be observed in the upper airways, ocular tissue, and skin. On the other hand, relatively insoluble gases such as phosgene, hydrogen sulfide, and oxides of nitrogen cause little upper-airway irritation or tissue damage and are much more likely to induce pulmonary edema, bronchiolitis, or alveolitis.³ Sustained low-level exposures to certain dusts, gases, and fumes may result in chronic fibrosing pulmonary disease such as asbestosis and silicosis. The immunologic mechanisms involved in the pathogenesis of these disorders are beyond the scope of this chapter.

PREVALENCE OF OCCUPATIONAL ASTHMA

There are few large population-based studies dealing with OA. Much of what has been published on the subject represents anecdotal case reports or descriptions of small clusters of cases. There are also a number of retrospective, observational studies dealing with specific industries. With some notable exceptions,⁴⁻⁶ there are no long-term, prospective, longitudinal studies of OA. In addition, nearly all epidemiological studies have relied upon subjective data in identifying bronchial asthma. Case definition has been variable in different parts of the world and in many instances it is not possible to ascertain whether minimally symptomatic, undiagnosed non-occupational asthma was present prior to any suspected work trigger. Equally problematic is whether pre-existing, asymptomatic BHR predisposed a worker to the development of adult-onset asthma secondary to a viral infection, exposure to a nonindustrial allergen, a pharmacologic agent, or a nonspecific environmental pollutant. There are many individuals who report having childhood asthma that completely abated, but recent studies have revealed that asymptomatic BHR in such patients may persist into adult life and cannot be modified with inhaled corticosteroids.⁷ Other studies have demonstrated that a number of young adults are underdiagnosed in adolescence and are later found to have asthma.⁸

An estimated 18 million individuals in the USA are said to have asthma. The prevalence of OA has been reported to range between 9% and 15% of the asthmatic population.⁹ A large population-based study of OA estimated that between 5% and 10% of cases of asthma among adults in European and other industrialized countries were due to work exposures.¹⁰ Unfortunately, the latter study did not distinguish between new-onset OA and pre-existing asthma that was aggravated due to a subsequent work exposure. There are better prevalence data for OA within certain industries. Understandably, the highest prevalence rates are in industries where workers are exposed to HMW agents. OA has been reported in up to 30% of laboratory animal workers, 16% of snow crab processors, 10% of isocyanate workers, and up to 9% of bakers, especially in Europe.¹¹

Many investigators believe the 5% prevalence for OA represents an underestimate. There are claims of some workers who develop OA but leave the industry without reporting the illness, creating a residual “healthy survivor population.” Other affected workers may remain on the job with OA, neglecting to report it for fear of losing their job or their seniority. Some workers with OA are said to be misdiagnosed with nonoccupational asthma. These scenarios must be balanced against the reality that in a setting where workers are protected by unions and state workers’ compensation statutes, it is highly improbable that any worker would remain silent with the possibility of an industrial injury. In addition, in the USA where some 40 million people remain uninsured, and even more underinsured, there is a tendency to implicate a work-related illness or injury as a mechanism for reimbursement in the evaluative process. Lastly, there is the occasional worker who abuses the system for personal gain.

GENETIC AND PREDISPOSING FACTORS

The development of atopy, asthma, and BHR is determined by multiple interacting genetic and environmental influences.¹² Atopy has been associated with an increased risk of sensitization and OA in workers exposed to enzymes, animal proteins, grains, flour, crab, latex, acid anhydrides,

Table 49.2 Categories of industrial agents causing occupational asthma with some representative examples and associated industries

Category of agent	Representative examples of agents	Related industry
Chemicals and plastics	Acid anhydrides	Industries using amine-based epoxy resins
	Phthalic	
	Trimellitic	
	Tetrachlorophthalic	
	Diisocyanates	Polyurethane, adhesives, catalyzed paint manufacturers; textile, chemical industries; manufacturers of wire coatings
	Toluene	
	Hexamethylene	
	Diphenylmethane	
	Diamines	Chemical, dental, rubber industries; manufacturers of abrasives; dental, rubber, electronics industries; resin makers
	Ethylenediamine	
	Piperazine	
	Triethanolamine	
	Formaldehyde	Lamination industry; adhesive manufacturing, plywood manufacturing
Metallic salts and dust	Formalin	
	Paraformaldehyde	
	Reactive azo-dyes	Textile industry
	Black GR	
	Orange 3R	
Wood/vegetable dusts	Complex platinum salts	Photography, jewelry, and refinishing industries
	Cobalt, vanadium	Hard metal, smelting industries
	Nickel salts	Metal plating industry
	Chromium	Cement, tanning industries
	Western red cedar (plicatic acid)	Sawmill industry, carpentry
	Flour	Food-processing industry; bakers, grain handlers, millers
	Green coffee bean	Food-processing industry; dock workers
	Castor bean	Oil, fertilizers industries
	Seeds	Food processing, oil product, carpet industries
	Cottonseed	
	Linseed	
	Flaxseed	
	Soybean	Food-processing industry; dock workers
	Vegetable gums (karaya, acacia, gum arabic)	Printing, chewing gum industries
	Colophony (abietic acid, pimaric acid)	Electronics industry
Pharmaceuticals	Cotton, hemp	Textile industry
	Antibiotics	Pharmaceutical industry; nursing
	β -lactam	
	Spiramycin	
	Tetracycline	
	Psyllium	Pharmaceutical industry; nursing
	Ipecac	Pharmaceutical industry; nursing
	Enflurane	Anesthesiology

Fig. 49.1 The health effects of any industrial exposure are dependent on the physicochemical properties of the agent involved along with its concentration, duration of exposure, and specific host factors. (From Bardana EJ. Occupational asthma. In: Lieberman PL, Biais MS (eds) Atlas of Allergic Disease, 2nd edn. Current Medicine LLC; 2005:195–204.)

green coffee, and castor bean. When LMW agents are involved, the data are less clear. The incidence of OA secondary to exposure to toluene diisocyanates (TDI), western red cedar, or trimellitic anhydride does not appear to be influenced by atopy. However, atopy does have a role in individuals exposed to other LMW agents such as complex salts of platinum, ethylenediamine, and dimethyl ethanolamine.¹³

Genetic research related to atopic linkages has shown allelic polymorphisms associated with genes encoding the β subunit of the high-affinity IgE receptor, regulatory cytokines, the β_2 receptor and the interleukin (IL)-4 α receptor.¹⁴ There is now consistent evidence that genetic polymorphisms that code for human leukocyte antigen (HLA) class II genes may predispose to OA to a number of agents. HLA associations indicate

Fig. 49.2 Highly soluble gases are likely to result in nasopharyngeal and laryngeal inflammation in addition to ocular irritation. Insoluble gases cause little upper-airway irritation or tissue damage and are more likely to result in pulmonary edema, bronchiolitis, or alveolitis. (From Bardana EJ. Occupational asthma. In: Lieberman PL, Biais MS (eds) *Atlas of Allergic Disease*, 2nd edn. Current Medicine LLC; Philadelphia, PA 2005:195–204.)

a specific immunologic response in OA induced by selected LMW agents, including western red cedar, complex platinum salts, trimellitic anhydride, and TDI.^{13, 15}

In addition, occupational agents may cause oxidative stress, and defects in antioxidant defenses that could contribute to the susceptibility of OA. It has been shown that absence of the MI polymorphism of glutathione-S-transferase (GST) (GSTM1-null genotype) is associated with an increased risk of isocyanate-induced asthma. It has been speculated that homozygosity for the GSTP1 valine allele could be a marker of reduced susceptibility for TDI-induced asthma.¹⁶

In addition to genetic factors, there are other predisposing issues related to the development of OA. A spectrum of industrial, climatic, personal, social, and other health factors have been identified as having the capacity to modulate the development of respiratory disease.

WORKPLACE FACTORS

These include the structure and inherent reactivity of the agents encountered in the workplace. Equally important are the employer's policies related to worker safety, i.e., access to material safety data sheets (MSDS), functional protective equipment, and enforcement of safety policies and appropriate industrial hygiene practices.

CLIMATIC CONDITIONS

Meteorological conditions can modify worker response to an inhaled antigen or irritant. Prevailing winds will determine the direction of an irritant stack emission. The presence of seasonal allergens or environmental pollutants (e.g., diesel exhaust particles) can augment the response to work-related antigens.¹⁷

TOBACCO AND RECREATIONAL DRUG ABUSE

Tobacco abuse continues to be a major problem in the USA, with an even greater prevalence in other parts of the world. The effect of smoking on the development of OA remains complex and controversial. A recent review by Siracusa et al. revealed little evidence of an increased risk of OA in workers who are smokers. However, there was evidence of an increased risk of new-onset sensitivity in smoking workers exposed to several HMW and LMW agents.¹⁸ Clearly there is an association between chronic smoking and a higher incidence of and morbidity from respiratory tract infections. Smoking also adversely impacts asthma by enhancing inflammation, increasing airway permeability and abrogating normal healing processes.

Chronic cannabis smoking is also quite prevalent and is associated with increased symptoms of chronic bronchitis and decreased lung function. There is also an additive effect between cannabis and tobacco abuse on adversely impacting the lung.¹⁹ Beyond these general adverse effects, nothing specific is known about the relevance of cannabis smoking to development of OA.

RESPIRATORY INFECTION

Viral infections are well recognized as important triggers of asthma exacerbations.²⁰ This must always be considered in the context of any worker presenting with suspected OA. Insights into the potential role of viral pathogens causing asthma have been enhanced by the employment of molecular detection techniques, i.e., polymerase chain reactions (PCR). In the 1970s viral infections were believed to be responsible for triggering 25% of asthma flares, whereas recent application of PCR detected viruses in 85% of reported episodes of cough, wheezing, and reduced peakflow.²¹ A number of mechanisms have been proposed to explain the association between viral infections and asthma, including direct epithelial injury, development of viral-specific IgE, and enhanced inflammatory mediator release. Bacterial infections of the paranasal sinuses are also associated with deterioration of underlying asthma.

NONSPECIFIC BHR

BHR is the physiologic hallmark of both nonoccupational and OA. Its presence correlates with bronchoalveolar inflammatory cell infiltrate, especially eosinophils and metachromatic cells. Prior observations that occupationally induced BHR intensifies with late-phase reactions triggered by industrial agents,²² and diminishes or normalizes after cessation of exposure,²³ suggest that BHR genetically predisposes to the development of OA. It is unclear whether the genetic tendency to non-specific BHR is a continuous physiologic state or whether it varies over time, fluctuating according to degrees of exposure to environmental agents. Preliminary data suggest that nonspecific BHR waxes and wanes according to a variety of extrinsic factors.

Although the measurement of BHR provides quantitative insight in variable airflow obstruction, the relationship between BHR and respiratory symptoms is weak. Approximately 50% of subjects with BHR report no respiratory symptoms. BHR follows a normal distribution throughout the population, with approximately 20% of individuals without evidence of asthma or other respiratory disease having mild BHR. Although nonspecific BHR is a feature of OA, it is clearly not diagnostic of asthma. Nonspecific BHR is present in individuals with a variety of other respiratory disorders, including viral respiratory infections, current and past tobacco abuse, chronic bronchitis, atopy without asthma, and hypersensitivity pneumonitis, among others.

The relationship between nonspecific BHR and asthmatic symptoms was the subject of a large study of nearly 1400 men employed in various industries. Approximately 60% of asymptomatic workers had a PC₂₀ at or below 8 mg/ml of methacholine. More importantly, approximately 35% of workers with physician-diagnosed asthma had a PC₂₀ greater than 8 mg/ml. Thus, the sensitivity of a PC₂₀ at or below 8 mg/ml in identifying physician-diagnosed asthma was 61% with a specificity of 85%. Ultimately, the positive predictive value of a methacholine challenge test to identify asthma was only 10%, but its negative predictive value was 99%.²⁴

CLINICAL, IMMUNOLOGIC, AND PATHOLOGIC FEATURES OF OCCUPATIONAL ASTHMA

From a clinical and pathologic perspective, new-onset OA can be divided into immunologic and nonimmunologic patterns. The immunologic class can be further divided into classic IgE-mediated and polyimmunologic

KEY CONCEPTS

SIGNIFICANCE OF NONSPECIFIC BRONCHIAL HYPERRESPONSIVENESS (NSBHR) IN THE DIAGNOSIS OF OCCUPATIONAL ASTHMA

NSBHR is regarded as a major characteristic of symptomatic asthma. NSBHR correlates with bronchoalveolar inflammatory cell infiltrates, especially eosinophils and metachromatic cells.

The genetic proclivity toward NSBHR may predispose individuals to the development of occupational asthma.

NSBHR probably waxes and wanes secondary to a variety of environmental and host influences.

NSBHR is found in normal, asymptomatic individuals, but is also associated with viral respiratory infections, cigarette smoking, exposure to certain pollutants (e.g., ozone), and a variety of disease states (see text).

The positive predictive value of NSBHR for the presence of asthma is only about 10%, whereas the negative predictive value is about 99%.

variants. The nonimmunologic category can be divided into RADS, reflex bronchoconstriction, and pharmacologic bronchoconstriction (Fig. 49.3).

ALLERGIC OR IMMUNOLOGIC OCCUPATIONAL ASTHMA

New-onset, allergic OA requires a latent period during which sensitization develops. Frequently, the exposure involves inhalation of soluble HMW proteins, glycoproteins, or other peptide-containing moieties, which in a predisposed individual result in the development of a specific IgE sensitization. There are a number of LMW agents capable of acting as haptens that cross-link with human protein to induce an IgE-mediated response. The initial step in the development of an allergic reaction is the interaction of a specific work allergen with IgE-sensitized mast cells, basophils, and other cells in airway tissue. IgE-sensitized mast cells secrete and generate bioactive mediators that facilitate development of allergic inflammation. The respiratory CD4 T cells produce predominantly type 2 helper (Th₂) cytokines IL-4, IL-5, and IL-13 that play essential roles in asthma by enhancing growth, differentiation, and recruitment of eosinophils, basophils, mast cells, and IgE-producing B cells. It has recently been found that the CD4 T cells in the lungs of patients with asthma express the receptor of invariant natural killer (NK) T cells that act in concert with conventional CD4 T cells modulating inflammation in asthma.²⁵ The hallmark response of invariant NK T cells is their rapid and copious production of cytokines, including interferon- γ , IL-4, IL-13, IL-5, granulocyte-macrophage colony-stimulating factor, and tumor necrosis factor- α . It is not known what roles invariant NK T cells play in OA, but these recent observations offer exciting opportunities for future research.

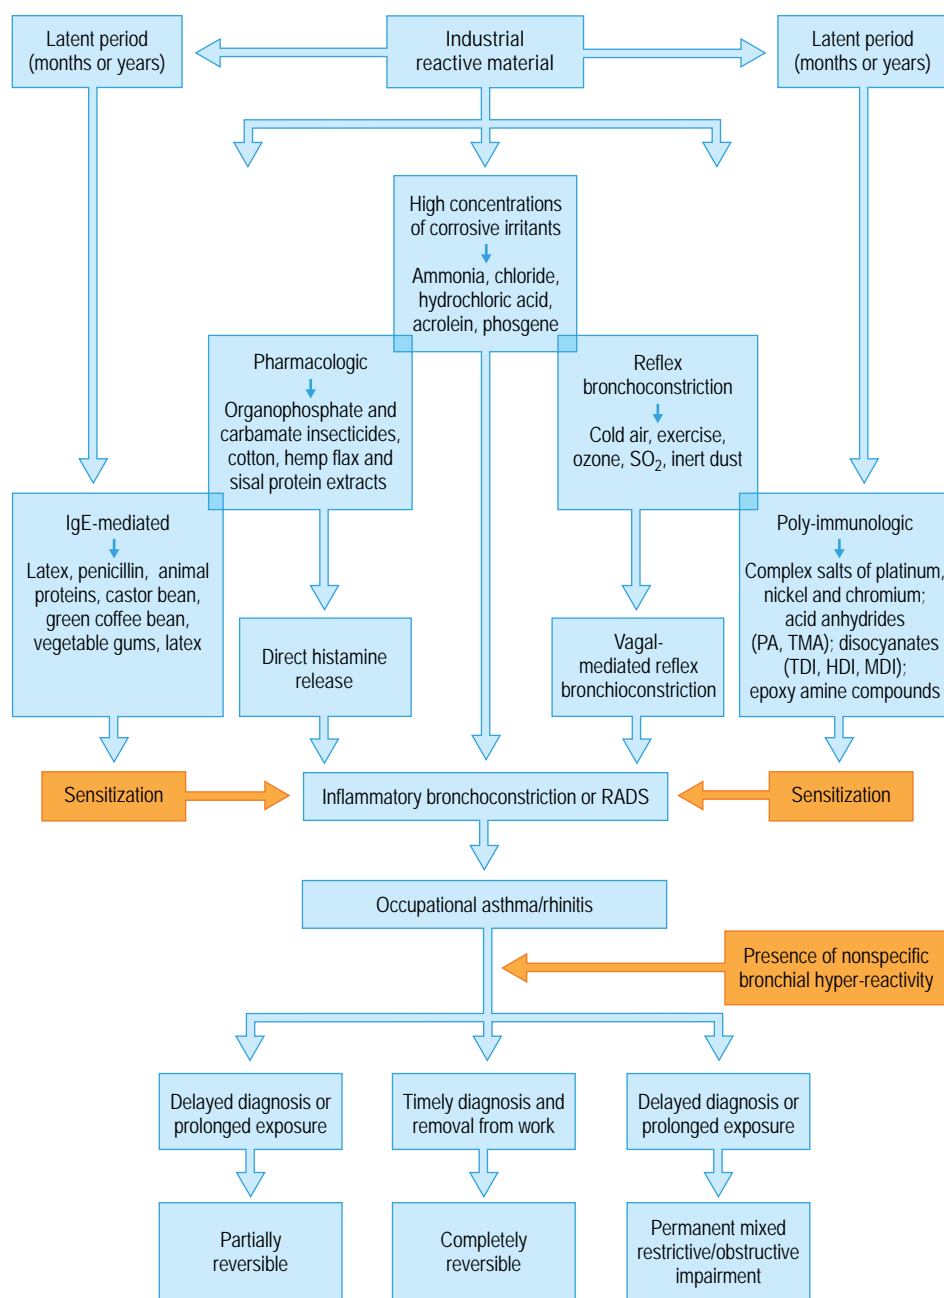

Fig. 49.3 Pathogenetic variants of occupational asthma (OA). Schematic diagram of the pathogenetic variants of OA depicting two basic mechanisms: immunologic and nonimmunologic OA. The latter has three subcategories: inflammatory, pharmacologic, and reflex bronchoconstriction. (Modified from Bardana EJ, Montanaro A. The pathogenesis and natural history of occupationally induced airway obstruction; pp 267–281. In: Bardana EJ, Montanaro A, O'Hollaren MT (eds) Occupational Asthma. Philadelphia: Hanley and Belfus; 1992, with permission.)

In addition to the classic IgE-mediated response to protein allergens, selected LMW agents are capable of inducing allergic OA by acting as copolymerizing agents producing limited immunologic responses. These include the complex salts of platinum, nickel, chromium, penicillin, and the epoxy amine compounds.

There are a group of LMW agents, including isocyanates, the acid anhydrides, and plicatic acid, that are capable of inducing immunologic OA, but the pathogenetic mechanisms are only partially elucidated.^{13, 26} One critical requirement common to all chemical allergens is the requirement to form a complex with protein. It is believed that chemical

KEY CONCEPTS

PATHOGENETIC MECHANISMS IN THE INDUCTION OF OCCUPATIONAL ASTHMA (OA)

OA is caused by two basic mechanisms: immunologically induced inflammation and several forms of irritant-induced inflammation

Most cases of OA result from exposure to work-related allergens

The majority of patients with allergic OA develop preceding or concomitant upper-airway and ocular symptoms

The allergic asthmatic response in OA is characterized by a pattern of early mast cell activation, eosinophil infiltration, fibroblast and collagen deposition, selective T-cell activation, epithelial sloughing, and mucous hypersecretion

Inflammatory bronchoconstriction and reactive airways dysfunction syndrome are similar, if not identical, disorders embodying nonimmunologic asthma

Most instances of OA are not a single, simple, or homogeneous entity, even when a single specific causal factor can be identified

Any given industrial reactant can probably induce OA by more than a single mechanism, and more than a single mechanism may be operative in any given patient

The pathogenesis of immunologic occupational asthma is similar to that of nonoccupational asthma

allergens are inherently protein-reactive, or must be converted at the tissue level into a protein-reactive moiety. By using the skin as a paradigm, it is assumed that chemical respiratory allergens access viable epithelium and form stable linkages with protein to become immunogenic.

Such chemical allergens must possess the innate ability to trigger type 2 immune responses resulting in sensitization of the respiratory mucosa and ultimately an allergic reaction. Recent studies have demonstrated an overexpression of matrix metalloproteinases (MMPs), including MMP-9, with resultant increase in airway inflammation and remodeling that results in the expression of asthmatic symptoms. As intimated above, there are also associations between respiratory allergy to certain chemicals and genes within the major histocompatibility complex (MHC) and, in particular, associations with genes coding for GSTs. In this respect, there is an apparent association between certain GST loci and OA to isocyanates.¹³ It is possible that glutathione, a ubiquitous intracellular and extracellular transfer agent, plays a role in the transport and binding of reactive chemicals to a variety of biologically important macromolecules. Despite these recent insights, there are many chemicals for which the pathogenesis of OA remains elusive. Two large groups of chemicals in this category include certain rare wood dusts and a variety of copolymerizing compounds or hardening agents used in the manufacture of resins or plastics. The development of animal models may facilitate a better understanding of the immunopathogenesis of OA induced by these agents.

The clinical presentation of the typical patient with new-onset, allergic OA frequently parallels the symptoms of patients with classic allergic disorders. After a latent period of months or years, many develop upper-airway and ocular symptoms of occupational rhinitis or rhinoconjunctivitis.

CLINICAL PEARLS

COMMON CORROSIVE OR NOXIOUS EXPOSURE AGENTS INCRIMINATED IN THE INDUCTION OF REACTIVE AIRWAYS DYSFUNCTION SYNDROME (RADS)

Chlorine
Phosgene
Sulfuric acid
Smoke inhalation
Phosphoric acid
Hydrochloric acid
Hydrogen sulfide
Metam sodium
Anhydrous ammonia
Toluene diisocyanate
Calcium oxide
Spray paint fumes (without isocyanates)

Asthma symptoms generally follow with work-related obstruction characterized by chest tightness, cough, and dyspnea, which may intensify during the work week.

NONIMMUNOLOGIC OCCUPATIONAL ASTHMA

The most common form of nonallergic OA is RADS, which results from a high-level exposure to a potent respiratory irritant at work. The onset is abrupt and is not associated with preceding ocular or upper-airway symptoms. Many of the incriminated agents are gases soluble in water and characteristically result in acute ocular, skin, and mucous membrane burns depending on the corrosive properties of the agent, the exposure concentration, and the duration of exposure. RADS was originally described by Gandevia in 1970²⁷ and referred to as "acute inflammatory bronchoconstriction." These early cases were related to accidental exposure to corrosive agents such as chlorine, hydrogen sulfide, and phosgene. Airflow obstruction followed within hours secondary to a chemically induced bronchitis or bronchopneumonia. In the initial descriptions, symptoms usually peaked within a week and usually regressed over the next several months. Some of these patients went on to manifest symptoms of chronic asthma or asymptomatic BHR. The symptom complex was redefined by Brooks and Lockey in 1981 when the term RADS was initially coined.²⁸ There was some initial controversy as to whether irritant-induced asthma was clearly distinguishable from allergic OA. After considerable case analysis, Alberts and dePico presented their rationale for relying on the American College of Chest Physicians (ACCP) Consensus Criteria²⁹ (Table 49.3). Because past and current tobacco abuse and atopy are independently associated with nonspecific BHR, and since the degree of BHR is not specified in the ACCP diagnostic criteria, five minor criteria (Table 49.4) have been

Table 49.3 Criteria for the diagnosis of reactive airways dysfunction syndrome**American College of Chest Physicians consensus (major criteria)²⁹**

Documented absence of preceding respiratory complaints
 Onset of symptoms after a single-exposure incident or accident
 Exposure to very high concentrations of a gas, smoke, fume, or vapor with irritant properties
 Onset of symptoms within 24 hours of exposure with persistence of symptoms for at least 3 months
 Symptoms simulating asthma with cough, wheeze, and dyspnea
 Presence of airflow obstruction on pulmonary function testing and/or presence of nonspecific bronchial hyperresponsiveness
 All other pulmonary diseases excluded

Minor criteria³⁰

Absence of an atopic state
 Absence of peripheral or pulmonary eosinophilia
 Absence of cigarette smoking for 10 years
 Bronchial hyperreactivity of moderate to severe degree (i.e., positive at methacholine concentration ≤ 8 mg/ml)
 Histopathology and/or bronchoalveolar lavage showing minimal lymphocytic inflammation

proposed which, if met, would strengthen the diagnosis considerably³⁰ (Table 49.3). There is growing support for the utilization of an 8 mg/ml concentration of methacholine as the upper limit for a positive test.

There are only limited pathologic studies related to RADS. Most of these studies have demonstrated a predominance of lymphocytes in bronchoalveolar lavage (BAL) with subepithelial thickening and fibrosis. The pathogenesis is postulated to be the result of extensive denudation of the bronchial epithelium with resultant airway inflammation. It is felt that nonspecific macrophage activation and mast cell degranulation result in the release of proinflammatory chemotactic and toxic mediators.

Nonallergic OA may also be secondary to agents producing a direct pharmacologic action on the respiratory mucosa (Fig. 49.3), e.g., organophosphate and carbamate insecticides. In sufficient doses, these agents inhibit acetylcholinesterase, which potentiates the effect of acetylcholine released from vagal fibers innervating bronchial smooth muscles and producing transient bronchoconstriction.

Reflex bronchoconstriction could be considered the third variant of nonallergic OA. It is distinguished from RADS by the intensity and nature of the exposure, i.e., chronic, low-to-moderate-dose, irritant-induced asthma. Certain chemicals and inert gases are felt to have the capacity to cause reflex bronchospasm by disrupting the delicate balance of adrenergic control involved in the maintenance of bronchial tone. However, it is unlikely that this mechanism induces new-onset OA. It is more likely operative in patients with pre-existent subclinical asthma, asymptomatic BHR, or atopy.³¹

■ PATIENT EVALUATION AND DIFFERENTIAL DIAGNOSIS OF OCCUPATIONAL ASTHMA ■

Though it has significant limitations, the medical history is a key element in the initial evaluation of OA. It should provide the examiner with clinical features of work-related airway disease and assist in confirming the linkage to one or more suspect work exposures. However,

both the work and home environment need to be simultaneously evaluated for potential exposure to allergens, irritants, chemicals, or organic dusts. Because of time limitations, a questionnaire may be helpful as an added tool to amplify the interview process. The worker (through his or her employer) should provide Material Safety Data Sheets (MSDSs) on all relevant exposures. A complete medical record review can be rewarding for two major reasons: (1) acquisition of information of which the worker had no awareness or recollection; and (2) to corroborate other important historical benchmarks.

In reaching final conclusions related to OA, the history alone has been found to be totally unacceptable. Though the history has been found to have a high degree of sensitivity (87%), it has a low specificity (22%) for the diagnosis of OA.³² Patient recall of past symptoms, illnesses, and medical care is often unreliable and inconsistent.

The physical examination should be carefully conducted to record the presence of ocular, nasal, oropharyngeal, and pulmonary abnormalities. It is not at all unusual for a worker with new-onset OA to have a normal examination. In those instances where the medical history is compelling, but the examination and spirometry are normal, an assessment of BHR can be useful.

LABORATORY STUDIES

The application of immunologic testing in the diagnosis of allergic OA is limited. The presence of allergen-specific IgE antibodies may be very helpful in the diagnosis and to some degree prognostication in the case of HMW allergens. However, data derived solely from cutaneous or serologic studies should not be used to conclude that a putative allergen was responsible for the OA. The presence of serum or skin-sensitizing antibody alone cannot be equated to the presence of a 'specific symptomatic state.' Antibodies of the IgG or IgE class are found in both symptomatic and unaffected workers and their value is that of a biologic marker of prior exposure. The clinician must utilize all the information assembled to differentiate between a state of asymptomatic sensitization and an active allergic symptom complex.

Table 49.4 Differential diagnostic considerations in establishing a certain diagnosis of work-related asthma**Immunologic causes of asthma**

Nonoccupational allergic asthma
 Allergic bronchopulmonary aspergillosis
 Churg–Strauss allergic granulomatosis

Infectious causes of asthma

Viral infection (rhinovirus, Rous sarcoma virus, and para-influenza types 1, 2 and 3)
Mycoplasma pneumoniae
Chlamydia pneumoniae

Pharmaceuticals (causative or trigger)

Aspirin and related nonsteroidal anti-inflammatory drugs (NSAIDs)
 β -adrenergic antagonists
 Sulfiting agents

Masqueraders of asthma

Organic toxic dust syndrome
 Acute tracheobronchitis
 Primary vocal cord dysfunction syndrome
 Secondary vocal cord dysfunction (e.g., gastroesophageal reflux)
 Hypersensitivity pneumonitis
 Chronic paranasal sinusitis

Conditions independently associated with asthma

Industrial bronchitis
 Emphysema
 Bronchiolitis obliterans

CHEST RADIOGRAPHS

Radiological observations have their principal utility in either excluding or implicating alternative conditions in the differential diagnostic process. The availability of high-resolution computed tomography has been invaluable in assessing the extent of coexisting emphysema, fibrosis, bronchiectasis, or other processes that may explain the presenting symptoms. Imaging studies may also be useful in delineating the presence of sinusitis which may be contributing to lower-airway symptoms.

PULMONARY FUNCTION STUDIES

Pulmonary function studies are essential in both the diagnosis and assessment of severity of OA. The diagnosis of OA demands as an initial premise an unequivocal demonstration of reversible airflow obstruction. The American Thoracic Society (ATS) criteria require a minimum 12% increase in forced expiratory volume in 1 second (FEV₁) with bronchodilator. When assessing spirometric data from various providers, the evaluator must consider possible inadequacies in the data. It has been shown that less than 20% of spirometry tests performed at primary care practices met ATS criteria. When spirometry is normal, methacholine provocation can be employed to demonstrate significant nonspecific

BHR. It must be carried out according to ATS criteria and positive responses at concentrations above 8 mg/ml concentration should be interpreted cautiously. In this respect, it is highly likely that exhaled nitric oxide (eNO) can be used as a safe and rapid assessment in the diagnosis of OA and eventually may replace methacholine challenge.³³

BRONCHIAL PROVOCATION STUDIES

The suspected temporal adverse effect of a putative work agent can be initially explored by serial determination of peak expiratory flow rates during a period of work abstinence and following a return to work. The information gleaned from such a study should be interpreted cautiously because the maneuver is effort-dependent and can be relied upon only when executed under direct observation using published guidelines. A more secure pragmatic approach would be to compare the degree of nonspecific BHR after a period of continuous occupational exposure with a baseline following a 3–4-week period of total abstinence from exposure to the suspected agent. Provided there are no significant changes in medication, a change in bronchial reactivity of more than two doubling concentrations (or doses) is considered significant. Alternatively, eNO could be used as the endpoint in this process, with a 20% increase in eNO at a flow rate of 250 ml regarded as significant. There are as yet

KEY CONCEPTS**CRITERIA FOR THE DIAGNOSIS OF *DE NOVO* OCCUPATIONAL ASTHMA**

Absence of pre-existing bronchial asthma
 Demonstration of variable airway obstruction
 Rational association of either allergic or irritant symptoms with an established work-related asthmagenic agent
 Demonstration of variable airway obstruction with exposure to the putative asthmagenic agent
 Controlled bronchial provocation with subirritant doses of incriminated industrial agent
 Regression of symptoms with timely diagnosis and removal from the incriminated agent

no studies in the occupational setting to verify the use of eNO, but these are likely to be reported in the near future. A third alternative would utilize cross-shift spirometric data, i.e., pre- and post-shift spirometry over the course of an entire work week.

The gold standard confirming the causal role of a specific work-related immunogen is a controlled bronchial challenge with subirritant concentrations of the suspected immunogen. The worker must be observed for immediate as well as delayed responses for 8–12 hours. These tests are invasive, time-consuming, pose some risk to the worker, and therefore must be performed with appropriate informed consent. A limited number of medical facilities are equipped and capable of performing this type of study.

DIFFERENTIAL DIAGNOSIS

Assuming that there has been a reliable demonstration of variable airflow obstruction by reliable physiologic testing, the clinician must consider the possibility that the asthma in question is not work-related. Pre-existent asthma should be excluded particularly in an individual with an atopic phenotype in whom asthma may have existed in a sub-clinical state or inappropriately labeled. Since OA is linked to causes and/or conditions at work, the examiner must exclude the possibility that the asthma is related to nonoccupational allergens or irritants. Other variants of asthma such as allergic bronchopulmonary aspergillosis, aspirin-sensitivity syndrome, and Churg–Strauss allergic granulomatosis must be excluded. Finally, unrelated disorders masquerading as asthma must be excluded. Chief among these disorders is vocal cord dysfunction (VCD). VCD is a common and frequently unrecognized masquerader and confounder of asthma. It may occur in up to 40% of patients who present with treatment-resistant asthma: one-quarter of these have isolated VCD, and the remainder have coexistent asthma. The diagnosis of VCD is dependent on a high index of suspicion related to the clinical presentation and the performance of flexible fiberoptic rhinolaryngoscopy during a symptomatic state in order to visualize the anterior portion of the vocal cords adducting during inspiration while the posterior glottis remains open (the so-called posterior chink). Other disorders that should be considered in the differential

THERAPEUTIC PRINCIPLES**PREVENTION AND MANAGEMENT OF OCCUPATIONAL ASTHMA**

Protect at-risk workers from potentially hazardous agents
 Institute regular surveillance
 When diagnosis is established, remove patient from all further exposure
 Treat residual symptoms in accord with usual asthma management

diagnostic process include chronic bronchitis, congestive heart failure, hypersensitivity pneumonitis, and organic dust toxic syndrome, among others (Table 49.4).

PREVENTION AND MANAGEMENT

The most effective manner of preventing OA is to protect at-risk workers from potentially hazardous exposures. This requires the employer to adopt and enforce optimum industrial hygiene measures that will reduce or eliminate ambient levels of known immunogens or respiratory irritants. This can be accomplished by mandating approved respirators that have been properly fit-tested, by installation of effective exhaust systems, or by development of enclosed and automated robotic processes. Many employers conduct surveillance of their workers and their industrial hygiene practices by regular measurements of potentially harmful agents and regular medical examinations focused on airway integrity (e.g., chest radiographs, spirometry).

Management of OA is identical to that of non-OA except the patient must be removed from further exposure to the causative agent in a timely manner. Therapeutically, a combination of anti-inflammatory and bronchodilator drugs is advocated. However, the use of pharmacologic treatment is not a substitute for complete avoidance.

PROGNOSIS

The major determinants of patient outcome include the total duration of exposure, asthma severity at diagnosis, and the pathogenic mechanisms operative in the original induction of OA.³⁴ In addition, coexisting factors such as cigarette smoking, chronic sinusitis, and gastro esophageal reflux disorder (GERD) may also play an important role as prognostic modifiers. Prompt removal of the patient with OA from the offending immunogen or irritant should result in clinical improvement (Fig. 49.3). Recently, Ameille and Descatha³⁴ reviewed the literature on the outcome of OA and reported a number of conclusions: (1) nonspecific BHR in OA generally improves following cessation of exposure and occurs over several years; (2) PC₂₀ or PD₂₀ methacholine at the time of diagnosis is the best predictor of BHR during subsequent follow-up; (3) prognosis does not appear to be influenced by the molecular weight of the causal agent; (4) continuing airway inflammation is associated with persistence of symptoms and nonspecific BHR;

and (5) significant reduction of immunogenic exposure could represent an acceptable compromise in instances where exposure cannot be totally avoided, but can be reduced to a threshold level at which the patient is unaware of ongoing symptoms. The majority of motivated patients who are diagnosed in a timely fashion and removed from further exposure achieve good control of their asthma and are capable of resuming full employment in an alternative job. This should parallel what generally happens in nonoccupational asthma when an avoidable allergen is removed, e.g., cat.

In instances where the diagnosis of OA is delayed, or where the worker refuses to comply with warnings regarding avoidance, chronic symptoms persist with concomitant pulmonary deterioration. It should be noted that *specific* BHR to an inciting agent may persist after removal from further exposure in individuals who are asymptomatic, who no longer use medications, and who lack *nonspecific* BHR.³⁵

Mechanisms of autoimmunity

Antony Rosen

50

Human autoimmune diseases occur frequently (affecting in aggregate more than 5% of the population worldwide), and impose a significant burden of morbidity and mortality on the human population.¹ Autoimmune diseases are defined as diseases in which immune responses to specific self-antigens contribute to the ongoing tissue damage that occurs in that disease. Both the specificity of the immune response and its role in tissue damage are central components of the definition. Autoimmune diseases may be either tissue-specific (e.g., thyroid, β -cells of the pancreas), where unique tissue-specific antigens are targeted, or may be more systemic, in which multiple tissues are affected, and a variety of apparently ubiquitously expressed autoantigens are targeted.²

Although the definition appears relatively simple in concept, the complexity of this spectrum of disorders is enormous, and has greatly challenged elucidation of simple shared mechanisms. This complexity affects almost every domain, including genetics, phenotypic expression, and kinetics. In the latter case, there is frequently a prolonged period (weeks to months) between initial onset of symptoms and development of the diagnostic phenotype, and disease may vary in expression in the same individual over time. However, in spite of this enormous complexity, there is a striking association of the clinical phenotype with the targets of the autoimmune response. This association is, in fact, so strong that autoantibodies have been used for diagnosis and prognosis in human autoimmune diseases.² For example, autoantibodies recognizing thyroid peroxidase are found in patients with autoimmune thyroiditis, autoantibodies to the Sm splicing ribonucleoprotein complex are diagnostic of systemic lupus erythematosus (SLE), and autoantibodies recognizing topoisomerase-1 are found in patients with the diffuse form of scleroderma. The immune response in autoimmune diseases has features of an adaptive immune response (usually directed against exogenous antigens), but its targets are autoantigens. Since the adaptive immune response is initiated when suprathreshold concentrations of molecules with structure not previously tolerized by the host are encountered in a proimmune context, the association of specific autoantibodies with distinct clinical phenotypes provides critical clues to understanding the initiation and propagation of autoimmune diseases.

This chapter highlights some of the mechanistic principles that underlie autoimmune diseases. The extraordinary breadth and complexity of this disease spectrum mean that the areas included cannot nearly encompass everything relevant.

■ THE DISTINCT PHASES IN THE DEVELOPMENT OF AUTOIMMUNITY ■

A major barrier to understanding mechanisms of autoimmunity comes from difficulty in defining early events in these diseases. Since diseases are only recognizable after development of the diagnostic phenotype, there has been the tendency to interpret findings made at diagnosis with findings present at initiation. By studying the development of autoantibodies over time in patients who subsequently manifest an autoimmune disease, significant recent data have demonstrated that this is only partly true, and that autoimmune diseases should be operationally viewed as having two phases—initiation and propagation.³ In the case of type I diabetes, development of islet cell autoantibodies frequently precedes diabetes, and additional islet cell autoantibodies accrue over time.⁴ Similarly, autoantibodies recognizing citrullinated proteins (rheumatoid arthritis (RA)-specific autoantibodies; see below) may precede the development of RA.⁵ These findings might indicate that a threshold needs to be exceeded in terms of tissue damage before symptoms manifest, or that there are two distinct phases in disease development, one marked by

KEY CONCEPTS

BARRIERS TO DEFINING MECHANISMS OF HUMAN AUTOIMMUNE DISEASE

- >> Genetic and phenotypic complexity
- >> Interval between initiating events and development of diagnostic phenotype

KEY CONCEPTS

AUTOANTIBODIES IN AUTOIMMUNE DISEASES

- >> Some autoantibodies precede the development of any symptoms by years (e.g., antinuclear antibodies and anti-phospholipid antibodies in systemic lupus erythematosus (SLE), anti-CCP in rheumatoid arthritis)
- >> Some autoantibodies only occur at around the time of onset of disease manifestations (e.g., anti-Sm and anti-RNP in SLE)
- >> There is a striking association of specific autoantibodies with distinct clinical phenotypes (e.g., anti-topoisomerase-1 with diffuse scleroderma and interstitial lung disease)

A	Susceptibility
<ul style="list-style-type: none">• Impaired tolerance induction• Impaired production of regulatory T cells• Altered immune signaling thresholds	
B	Initiation
<ul style="list-style-type: none">• Suprathreshold concentration of autoantigens• Non-tolerized structure• Pro-immune context - infection, malignancy, exposure to adjuvants	
C	Propagation
<ul style="list-style-type: none">• Acquisition of adjuvant properties by disease specific autoantigens• Increased autoantigen expression in the target tissue• Immune effector pathways generate/expose autoantigen, which further drives the immune response	

production of a group of autoantibodies, the second by autoamplifying tissue damage. In a landmark study in SLE, Harley and colleagues have provided important insights into this issue.³ They analyzed sera collected from patients in the US military who subsequently developed SLE. Strikingly, autoantibodies in SLE could be divided into two groups: (1) those that precede the diagnosis of SLE by several years—these included antinuclear antibodies and antiphospholipid antibodies; and (2) those which occurred around the time of onset of symptoms—these included anti-Sm, anti-RNP, and, to a lesser extent, anti-DNA. The observation that one group of autoantibodies precedes symptoms in SLE and that another group appears coincident with the phenotype strongly suggests that the groups mark distinct events in the development of autoimmune disease. Members of the first group are likely markers of disease initiation; members of the second group are likely markers of disease propagation. The antigens targeted by the immune system in this latter phase (i.e., associated with clinical disease) are more likely to have some function in disease propagation, possibly through their possession of proinflammatory or adjuvant functions⁶ (see below).

It is therefore useful to examine the development of autoimmune diseases in four phases (Fig. 50.1):

1. Susceptibility phase—before disease, but where one or several preconditions for later initiation are satisfied. This includes impaired tolerance induction, or altered immune signaling thresholds. The susceptibility phase can be either inherited or acquired (and in many diseases, both), permanent or transient.
2. Initiation phase—before onset of clinical disease, but marked by the presence of an autoimmune response (e.g., in the case of SLE—antiphospholipid antibodies).
3. Propagation phase—this corresponds with the onset of clinical disease, marked by propagation-specific immune responses (e.g., in the case of SLE, anti-Sm antibodies).

Fig. 50.1 Autoimmunity: the free-energy model. Autoimmune diseases result from a complex interplay of pathways and events which initially allow autoreactivity to manifest (A), and then, after an initiating event (B), allow development of self-sustaining tissue damage (C). Each of these phases can be viewed as “energy states.” Initiation does not occur spontaneously, but requires displacement from equilibrium through exogenous stimuli. The amount of energy input in an autoimmune host required for initiation is lower than that needed in a normal host, where the barriers restraining development of autoimmunity are very stringent. Factors that can decrease the “activation energy” for initiation include abnormalities in tolerance induction, regulatory T-cell (Treg) development, or immune signaling thresholds. Disease initiation is marked by the presence of autoimmunity, but precedes the diagnostic clinical phenotype. The propagation phase—the lowest energy state—is marked by a feed-forward cycle of autoimmunity and tissue damage, in which immune effector pathways cause damage and provide antigen to drive the ongoing immune response. This phase no longer requires significant exogenous energy input to maintain the cycle. In normal hosts, pathways of immunoregulation may dampen this feed-forward loop, and allow resolution to occur (D). Such immunoregulation is likely absent or fails in autoimmune hosts.

4. Regulation/resolution phase—it should also be noted that in many cases during disease propagation, immunoregulatory pathways are also activated, which may result in natural inhibition of clinical disease over time. In rare cases, these inhibitory pathways can lead to permanent resolution. This resolution phase will not be discussed further here but its existence provides important evidence that homeostasis can be re-established even after the amplified phenotype develops.

PHASE I: SUSCEPTIBILITY

Although autoimmune diseases in humans are genetically complex, significant advances in understanding have occurred over the past several years. In some cases, advances have come from the study of autoimmunity with mendelian patterns of inheritance (e.g., APECED, IPEX, C1q deficiency). Advances have also come from genetic association studies of various autoimmune phenotypes (e.g., SLE, type I diabetes mellitus). There have also been important advances in the genetics of autoimmunity in several mouse models. These studies highlight a critical role for pathways of tolerance induction, immunoregulation, and setpoints/thresholds for immune signaling in avoiding emergence of autoimmunity.

Incomplete thymic tolerance induction predisposes to autoimmunity

Significant insights into basic mechanisms can derive from the study of rare human phenotypes. This has been true for autoimmunity, where several monogenic disorders have defined important pathogenic principles. Autoimmune polyendocrine syndrome type I (APS1), also called autoimmune polyendocrinopathy candidiasis ectodermal dystrophy (APECED), is a rare disease in which patients develop multiple autoimmune diseases, often beginning in childhood.⁷ While candidiasis and ectodermal dystrophy (including involvement of enamel and nails, as well as keratopathy) are features of the disease, the syndrome is characterized by striking autoimmunity directed against multiple different target tissues. Autoimmune processes include autoimmune hypoparathyroidism, Addison's disease,

autoimmune gastritis with pernicious anemia, type I diabetes, thyroid disease, autoimmune hepatitis, and celiac disease, as well as gonadal failure. Numerous autoantigens have been defined as targets of autoimmunity in APS1, and include enzymes specifically expressed in various endocrine tissues (e.g., steroid 21-hydroxylase, specific for adrenal cortex; steroid 17 α -hydroxylase, found in adrenal cortex and gonads; GAD65, found in pancreatic islets, and thyroid peroxidase). The genetic basis of APS1 was mapped to a gene on chromosome 21q22.3, subsequently termed *AIRE* (for autoimmune regulator). *AIRE* expression is highest in the thymus, where it is expressed in medullary thymic epithelial cells. Several predicted structural features of the *AIRE* protein and its localization in nuclear dots suggested that the protein might be a transcriptional regulator; and significant evidence for this proposal was obtained *in vitro*. Several *AIRE*-deficient mouse models were subsequently generated, which allowed the definition of important pathogenic pathways in APS1 that are likely broadly relevant to the mechanisms of autoimmunity in general. Thus, mice deficient for *AIRE* developed various autoimmune phenotypes, resembling those found in human APS1. These included multiorgan lymphocytic infiltration, autoantibodies, as well as autoimmune eye disease. In an elegant series of experiments, Mathis and colleagues demonstrated that *AIRE* regulates expression in thymic epithelial cells of various peripheral autoantigens normally expressed exclusively in endocrine target tissues.⁸ Thus, *AIRE* appears to control the ectopic expression in the thymus of tissue-restricted autoantigens, and to provide an antigen source against which to establish central tolerance.⁸

In recent studies, additional strong support for this model has been provided. Anderson and colleagues demonstrated that autoimmune eye disease in *AIRE*-deficient mice develops as the result of loss of thymic expression of a single eye antigen, interphotoreceptor retinoid-binding protein (IRBP).⁹ Interestingly, lack of IRBP expression in the thymus, even in the presence of *AIRE* expression, is sufficient to induce eye-specific autoimmunity. These data demonstrate that expression of peripheral autoantigens in the thymus constitutes a major barrier to the subsequent development of autoimmunity against these peripheral sites. Although it is likely that similar principles apply to ubiquitously expressed autoantigens targeted in systemic autoimmune diseases, there are currently minimal data directly addressing this issue.

Impaired clearance and tolerance induction by apoptotic cells: susceptibility defect in systemic autoimmunity

Although little is known in humans about the thymic pathways of tolerance induction to ubiquitously expressed autoantigens, there is accumulating evidence to suggest that in the periphery apoptotic cells play an important role in providing a source of autoantigens against which the organism becomes tolerant.¹⁰ Apoptotic cells are generally very efficiently cleared by phagocytic cells; these events are normally associated with the production of anti-inflammatory cytokines and result in tolerance induction.¹¹ Interestingly, early components of the classical complement pathway (e.g., C1q and C4) and C-reactive protein are required for efficient apoptotic cell clearance, with production of interleukin-10 (IL-10) and transforming growth factor- β (TGF- β). It is of particular note therefore that homozygous C1q deficiency is associated with a striking susceptibility to SLE, suggesting that rapid, efficient, tolerance-inducing clearance of apoptotic cells may play a similar role to *AIRE* expression in the thymus in preventing subsequent emergence of

KEY CONCEPTS

MECHANISMS UNDERLYING SUSCEPTIBILITY TO AUTOIMMUNITY

- >> Incomplete induction of tolerance in the thymus to peripherally expressed autoantigens (*AIRE* deficiency causing autoimmune polyendocrinopathy candidiasis ectodermal dystrophy (APECED) syndrome)
- >> Impaired clearance and tolerance induction by apoptotic cells (e.g., deficiency of C1q, C4, MFG-E8, Mer)
- >> Defective production of regulatory T cells (FOXP3 deficiency causing immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome)
- >> Altered immune signaling thresholds (e.g., CTLA-4 polymorphisms, PTPN22 polymorphisms)

autoimmunity to ubiquitously expressed autoantigens.¹² Additional support for this model comes from recent studies of milk fat globule-EGF factor 8 (MFG-E8), a glycoprotein secreted from macrophages that is required for the efficient attachment and clearance of apoptotic cells by macrophages and immature dendritic cells. MFG-E8 is also expressed in tingible-body macrophages in the germinal centers of secondary lymphoid tissues. Interestingly, many unengulfed apoptotic cells are present in the germinal centers of the spleen in MFG-E8-deficient mice, which develop a striking lupus-like phenotype.¹³ Other examples exist in which defects in clearance of apoptotic cells are associated with development of systemic autoimmunity (e.g., Mer deficiency). Together, the data strongly suggest that efficient, anti-inflammatory clearance of apoptotic cells plays a central role in tolerance induction and prevention of autoimmunity.

Defective production of Treg cells

Although pathways exist that: (1) regulate autoantigen expression at sites of tolerance induction; and (2) guide autoantigens towards tolerance-inducing outcomes, these pathways alone are clearly insufficient to prevent the emergence of autoimmune disease. This fact is highlighted by the emergence of autoimmunity when regulatory T-cell (Treg) differentiation is abnormal in humans with immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome, the human equivalent of the *scurfy* mouse. IPEX is a rare, X-linked recessive disorder that is characterized by type I diabetes, thyroiditis, atopic dermatitis, and inflammatory bowel disease, and is caused by mutations in the *FOXP3* gene.¹⁴ *FOXP3* is a member of the forkhead family of transcription factors, and is essential for the development of Tregs, which regulate the activation and differentiation of effector T cells at many different levels. It is therefore likely that induction of tolerance is incomplete under most circumstances, and that self-sustaining autoimmunity is limited by Treg function.

Signaling thresholds and susceptibility to autoimmunity

Several modulators of T-cell signaling have also been defined as important susceptibility determinants in autoimmunity (reviewed in reference 15). For example, CTLA4 polymorphisms are associated with increased risk of a variety of autoimmune diseases, including type I diabetes, Graves disease and rheumatoid arthritis. Similarly, a functional polymorphism in PTPN22 has been identified as a major risk factor for several human autoimmune diseases, including SLE, rheumatoid arthritis and type I diabetes. Although the exact mechanisms underlying susceptibility to autoimmunity remain unclear, in both cases the polymorphisms appear to regulate the balance of stimulatory and inhibitory signaling in effector and regulatory T cells, favoring effector T-cell activation.

There are therefore many barriers to the development of autoimmunity, including effective tolerance induction in the thymus and periphery, tightly regulated immune signaling, and homeostatic pathways of immunoregulation to limit self responses should these occur. It is likely that the genetic susceptibility to autoimmunity in outbred humans represents an integrated threshold involving genes that regulate these various pathways, upon which environmental and stochastic events act to accomplish disease initiation and propagation.

PHASE 2: INITIATION

Initiation of an adaptive immune response requires presentation to T cells of suprathreshold concentrations of molecules with structure not previously tolerized by the host. Such tolerance requires generation of self-determinants in sufficient amounts to be recognized by T cells undergoing deletion in the thymus or anergy in the periphery. One of the more persuasive models proposed to explain the persistence of potentially autoreactive T cells within the repertoire of the host is that of immunodominance of T-cell epitopes. This model provides major insights into the pathogenesis of autoimmunity.^{15, 16}

Dominance and crypticity

Studies by Sercarz and colleagues¹⁶ have stressed that, while antigens contain numerous potential determinants that could be presented on major histocompatibility complex (MHC) class II during antigen processing, not all determinants in a particular molecule are equally likely to be efficiently presented. Those determinants that are most efficiently presented are termed 'dominant'; those that are not loaded on to class II to a significant degree are termed 'cryptic.' Since pathways of antigen processing are relatively constant, the outcome in terms of epitope selection for any particular autoantigen-MHC class II combination is predictable and reproducible. For self-antigens, it is likely that a constant set of dominant determinants are generated during antigen processing under most circumstances, with similar outcomes in the thymus and periphery. Antigens processed by the "standard" pathway are therefore fully tolerized, with the T-cell repertoire purged of reactivity to the dominant self. However, since the balance of dominant and cryptic epitopes is significantly influenced by protein structure, post-translational modification, and folding, changes of protein structure may alter the balance of dominant and cryptic determinants that are presented during natural antigen processing. Relevant changes include proteolysis and various post-translational modifications as well as complex formation (including antibodies and other binding partners: see below). Under such conditions, previously cryptic determinants may be revealed, and may stimulate T cells recognizing autoantigens.

KEY CONCEPTS

MECHANISMS THAT CAN ALTER ANTIGEN PROCESSING TO REVEAL CRYPTIC EPITOPES

- >> Modification of autoantigen processing through high-affinity binding to ligands or antibodies
- >> Distinct proteolytic machinery in the thymus and periphery or differential modification of proteolytic activity
- >> Modification of autoantigen structure which modifies its processing by endogenous antigen-presenting cell machinery, generally through post-translational modifications
- >> Novel proteolytic events not present in the normal antigen-presenting cell pathways, e.g., novel cleavage during cell death or damage or inflammation
- >> Novel forms of autoantigens generated by mutation, truncation, or splicing

It is likely that this paradigm is broadly applicable to autoimmunity, since numerous changes in autoantigen structure occur during various relevant physiological states, and can influence subsequent processing and selection of epitopes presented.¹⁷ Several potential mechanisms that may alter antigen processing to reveal potentially cryptic epitopes are summarized below:

1. Modification of autoantigen processing through high-affinity binding to ligands or antibodies. Several studies have demonstrated that antigen processing can be dramatically altered when the antigen binds with high affinity to a ligand or antibody. Simitsek et al.¹⁸ demonstrated that presentation of T-cell determinants in tetanus toxin can be either enhanced or suppressed as a direct consequence of antibody modulation of antigen processing in human B lymphoblastoid cells. Remarkably, a single bound antibody could simultaneously enhance the presentation of one T-cell determinant by more than 10-fold while strongly suppressing the presentation of a different T-cell determinant. Biochemical analysis showed that both the suppressed and boosted determinants fell within an extended domain of antigen stabilized by this antibody during proteolysis.¹⁸ Thus, ligand-induced changes in processing can destroy dominant determinants or reveal cryptic self-determinants. Similar observations have also been made with numerous other antigen-binding partners, including human immunodeficiency virus (HIV) gp120 and CD4 (with consequent autoimmunity to CD4), and p53-SV40 large T-antigen complexes.¹⁷
2. Distinct proteolytic machinery in the thymus and periphery or differential modification of proteolytic activity. Watts and colleagues showed that a principal human leukocyte antigen (HLA)-DR2-restricted epitope in myelin basic protein (MBP-MBP⁸⁵⁻⁹⁹) contains a processing site for asparagine endopeptidase (AEP), with cleavage by AEP abolishing the epitope. AEP activity is therefore a critical factor in presentation of this epitope.¹⁹ In human antigen-presenting cells (APC), presentation of MBP⁸⁵⁻⁹⁹ is inversely proportional to the amount of cellular AEP activity, and inhibition of AEP greatly enhances presentation of the MBP⁸⁵⁻⁹⁹ epitope. Interestingly, both MBP and AEP are expressed in the thymus, AEP at abundant levels. These data suggest that this major epitope in neurological autoimmunity may not be presented under normal circumstances in the thymus due to destruction by AEP, therefore raising the potential for later presentation in the periphery in the setting of decreased AEP activity.
3. Modification of autoantigen structure which modifies its processing by the endogenous APC machinery: various post-translational modifications. It has been known for some time that autoantigens undergo a variety of post-translational modifications, including phosphorylation, proteolytic cleavage, ubiquitination, transglutamination, citrullination, and isoaspartyl modification.²⁰⁻²² In several cases, autoantibodies recognize exclusively the modified form of the antigen (e.g., RNA polymerase-II large subunit, SR proteins, citrullinated vimentin and other rheumatoid arthritis autoantigens), indicating that the modified forms of the molecules are important in driving the immune response. Little is known about the circumstances in which such modified antigens are generated in the relevant target tissue *in vivo*, although various pathways of cell injury and death have been proposed to be important in this regard. Doyle and Mamula²⁰ demonstrated that post-translational modification of autoantigen structure may be much more broadly relevant than can be appreciated by studying autoantibody specificity alone. Their studies

centered on the effect of isoaspartyl modifications on antigen processing and presentation. They showed that mouse immunization with a murine cytochrome c peptide (amino acids 90–104) showed no T- or B-cell response. In contrast, immunization with the isoaspartyl form of this peptide resulted in strong T- and B-cell responses. While the autoantibodies that were elicited recognized both the modified and the native form of the antigen, T cells only recognized the isoaspartyl form. Similar observations have also been made for several SLE autoantigens. The difficulty of detecting and quantifying antigen-specific T cells in various autoimmune diseases may reflect their preferential recognition of subtly modified forms of autoantigen. This is an important area for future study—currently there is no systematic way of generating the relevant autoantigen forms.

4. Novel proteolytic events not present in the normal APC pathways, e.g., novel cleavage during cell death or damage or inflammation. Recent studies have provided evidence that single proteolytic events early in the process of antigen processing may play critical roles in defining the epitopes generated. For example, Watts and colleagues conclusively demonstrated that early cleavage by AEP—a protease in the lysosomal pathway that cleaves substrates after asparagines—determines subsequent proteolytic events, and thus which epitopes are selected during natural processing of whole antigens. Modifications of the antigen that affect this early cleavage dramatically change the epitopes loaded on to MHC class II.²³

This property creates significant potential to load distinct epitopes if unique proteolytic activities are expressed in different tissues or inflammatory microenvironments. Activated inflammatory cells constitute a major source of such proteases, including various cytotoxic lymphocyte granule proteases (granzymes), as well as numerous neutrophil and monocyte granule proteases. It is of interest that numerous autoantigens targeted in systemic autoimmune diseases are substrates for these inflammatory proteases, and that unique autoantigen fragments are generated through the activity of granzyme B and potentially other similar proteases.²⁴ Such autoantigen forms are not generated during other forms of cell damage or death. Furthermore, similar activity is not observed against nonautoantigens, suggesting that novel proteolytic cleavage of intracellular autoantigens during activity of cytotoxic immune effector pathways may provide a source of cryptic epitopes not generated during homeostatic “tolerance-inducing” tissue turnover. Direct evidence that inflammatory protease-mediated revelation of cryptic epitopes is relevant to initiation of autoimmunity *in vivo* is still needed.

5. Novel forms of autoantigens generated by mutation, truncation, or splicing. Since the final epitopes generated and loaded on to MHC class II can be profoundly influenced by single early cleavage events during antigen processing, relatively minor but critically placed changes in the primary structure of autoantigens may have the capacity to influence peptide selection. A recent study of the melanoma and vitiligo-associated autoantigens (tyrosinase-related proteins 1 and 2) has strikingly demonstrated that this mechanism may play an important role in generating immune responses to self and tumor antigens.²⁵ In this study, Engelhorn and colleagues studied whether mutated-self gene products are more likely to initiate immunity, and used a systematic approach to define some of the principles that determine this. They used an error-prone polymerase in polymerase chain reactions to generate cDNA libraries encoding large numbers

of random mutations in syngeneic TRP proteins. Individual gene copies had a mean of 15–20 mutations, and each copy was predicted to contain a unique set of mutations. The investigators then used a DNA immunization approach into black mice to test the immunogenicity of pools of mutated cDNAs, by looking for the development of vitiligo or resistance to melanoma challenge. Immunization with nonmutated proteins induced no detectable immune responses, consistent with establishment of tolerance to the full-length molecules. In contrast, the DNA pools elicited both autoimmune depigmentation and the ability to reject tumors. Additional analysis showed that autoimmunity resulted from mutations that altered autoantigen cell biology, particularly as regards degradation rates and pathways. Mutations also created new helper T-cell epitopes, and induced recognition of nonmutated but previously cryptic epitopes. Interestingly, mutations themselves did not form part of CD8 epitopes that drive the anti-self and anti-tumor immune responses. Mutated molecules that were immunogenic were frequently truncated, leading the authors to propose that inappropriately truncated self-proteins may provoke autoimmunity when present in a proinflammatory environment. Although there are not yet good examples where natural autoimmunity arises due to the progressive accumulation of somatic mutations over time, with the expression of mutant, truncated forms of autoantigens, this study does provide an important mechanistic underpinning for the proposal that accumulated mutations have a role in the initiation of autoimmunity.

Indeed, there are substantial data that link autoimmunity and cancer. While many initial reports of a temporal association of malignancy and various autoimmune processes were anecdotal, and thought to be chance observations, evidence demonstrating that this relationship is real and likely of mechanistic significance has been growing. For example, the association of cancer with dermatomyositis is present in ~20% of individuals with dermatomyositis, with a striking temporal clustering of cancer diagnosis around the time of diagnosis of the myositis.²⁶ Similarly, there is evidence for an association of SLE with cancer, particularly lymphoma, again clustered within the first 2 years of SLE diagnosis.²⁷ These associations, both with timing of diagnosis as well as preferentially with specific tumor types, are strongly indicative of a non-random clustering of potential mechanistic significance. There is also growing evidence that, when associated with ‘paraneoplastic’ autoimmune syndromes, cancers are frequently smaller at the time of diagnosis and thus may have a better prognosis. Perhaps the most striking evidence for a potential mechanistic association between autoimmunity and effective anti-cancer immunity comes from recent studies showing that development of autoimmunity during immunotherapy for a variety of different cancers is a very striking predictor of a better cancer outcome. This is true for metastatic melanoma, where development of vitiligo is a predictor of an effective anti-tumor response.²⁸ Perhaps even more striking is the recent observation that this powerful anti-cancer response is observed not only when autoimmunity to melanocytes is induced, but also when immunotherapy (in this case using systemic high-dose adjuvant interferon- α_{2b} therapy) induces evidence of systemic autoimmunity (defined by newly detected autoantibodies).²⁹

The likelihood that the significant accumulation of somatic mutation with age in human populations and its association with malignancy play important roles in the genesis of some forms of human autoimmunity is very high. Additional studies to confirm this and elucidate the underlying

mechanisms remain a high priority. However, the barriers to such studies in humans are very significant, as effective anti-cancer immunity may be phenotypically silent, and convenient technologies to quantify somatic mutation and specific immune responses in normal individuals will be needed to draw conclusions of causality.

Antigen mimicry

The process of antigen mimicry (see below) has frequently been proposed as a potential initiator of autoimmune diseases.^{30, 31} This mechanism, particularly when isolated, is only likely relevant to those autoimmune processes clearly associated with antecedent infections, and particularly those that resolve spontaneously and subsequently recur upon re-exposure to the offending agent. The mechanism may, however, also play a role in initiation of the autoimmune response in self-sustaining autoimmune processes, but in this case, requires that T-cell responses to the cross-reacting self-antigen are initiated.

Foreign antigens, which often differ from their homologous self-antigens in some areas, may nevertheless bear significant structural similarity to self-antigens in other regions. Initiation of an immune response to the foreign antigen may generate a cross-reactive antibody response that also recognizes the self-protein (antigen mimicry). When the antigen is a cell surface molecule, antibody-mediated effector pathways can lead to host tissue damage. Although the antibody response is cross-reactive with self-molecules, the T cells that drive this response are generally directed at the foreign antigen, at least initially (see below). Diseases involving this sort of “antigen mimicry” therefore tend to be self-limited, although they can recur upon re-exposure to the offending antigen. It is important to realize that antigen mimicry alone cannot explain self-sustaining autoimmune diseases, which are driven by self-antigens and autoreactive T cells. In these cases, there is a requirement for overcoming T-cell tolerance to the self protein. The central issues in this regard are: (1) how T-cell tolerance to self-antigens might initially be broken; and (2) once this has occurred, why these antigens continue to drive the immune response to self. The simultaneous liberation of self-antigen in the presence of the cross-reactive antibody response has been proposed to play critical roles in this regard. For example, several studies suggest that when a humoral response to a foreign protein is induced that cross-reacts with the self-antigen, a strong helper T-cell response specific for the self-antigen can occur. The simultaneous liberation of significant amounts of self-antigen in the setting of a cross-reactive antibody response may allow effective presentation of cryptic epitopes in the self-antigen to autoreactive T cells by activated cross-reactive B cells. If continued release of self-antigen occurs, a specific, adaptive immune response to self will be sustained. Antigen release from tissues likely plays a critical role in driving this autoimmune process. Understanding the mechanisms of ongoing antigen release at sites of tissue damage in autoimmune disease (e.g., unique pathways of cell injury and death) is a high priority for future work, as it provides a novel target for therapy (see below).

It is clear from the above discussion that extraordinary complexity is operative in initiation of the human autoimmune diseases. The patient population is genetically heterogeneous, the human immune system is complex and extremely plastic, and it interacts with a plethora of environmental stimuli and stochastic events. The simultaneous confluence of susceptibility factors and initiation forces to set off the self-sustained and autoamplifying process is therefore a rare occurrence. In contrast, once

Fig. 50.2 The propagation phase in autoimmune diseases. Target cells in normal tissues express low levels of autoantigens. Under conditions of stress, damage, and exposure to cytokines, antigen levels increase, likely associated with changes in antigen structure (various post-translational modifications). Furthermore, type I interferons sensitize target cells to killing pathways, maximizing antigen release through apoptosis or other forms of cell death. Autoantigens released from this perturbed target cell have adjuvant capacity. In the setting of the immune response generated during the initiation phase, this dual property of autoantigens allows effective stimulation of plasmacytoid DCs (pDC), which secrete type I interferons (IFN) in large amounts. Type I IFNs have multiple effects which conspire to drive additional immune responses to self (including B and T cells), regulate monocyte (mono) differentiation into mature antigen-presenting DCs, increase target cell killing, and enhance autoantigen (Ag) expression. These multiple interacting loops that reinforce each other likely play important roles in generating self-sustaining tissue damage.

activation of autoreactive T cells has occurred, the ability of the immune system to respond vigorously to low concentrations of antigen, to amplify the specific effector response to those antigens, and to spread the response to additional antigens in that tissue, greatly reduces the stringency that must be met to keep the process going.

PHASE III: PROPAGATION (FIG. 50.2)

Principles of amplification

One of the central features of human autoimmunity is the tendency of the process to amplify progressively with the accumulation of significant immune-mediated tissue damage. Furthermore, in the vast majority of cases, once such amplification begins, the process is very unlikely to resolve spontaneously. Properties of autoantigens themselves may be very important in this phase, in terms of both acquisition of adjuvant properties, as well as regulation of expression. The essential features of amplification are a substrate cycle, in which antigen expression and adjuvant properties induce an immune response, which induces increased antigen expression and tissue damage, further driving the immune response. The importance of tissue-specific autoantigen expression in focusing such immune responses is only beginning to be recognized.

Acquisition of adjuvant properties by disease-specific autoantigens

In spite of the fact that tens of thousands of molecules could be targeted by the immune system in autoimmunity, the number of molecules that are frequently targeted in the different phenotypes are markedly restricted—limited perhaps to 100 or so molecules. This has led to the proposal that frequently targeted autoantigens may themselves have properties that make them proimmune. Recent work by Howard et al provided important support for this proposal (reviewed in reference 32). They observed that the autoantigenic histidyl aminoacyl tRNA synthetase (HRS), which is targeted in autoimmune myositis (but not nonautoantigenic lysyl- and aspartyl-aminoacyl tRNA synthetases), is chemoattractant to immature dendritic cells and other leukocytes. In the case of HRS, chemoattraction occurs in a CCR5-dependent way. The authors suggested that the selection of a self-molecule as a target for an autoantibody response may be a consequence of proinflammatory properties of the molecule itself. Plotz further suggested that modification of autoantigen structure during processes of cell damage or death may be critical in recruiting these additional functions of autoantigens.

One of the most likely receptor systems to sense and transduce the proinflammatory properties of autoantigens is the Toll-like receptor (TLR) family, which is the primary innate immune system transducer of pathogen-associated molecular patterns^{6, 33} (Chapter 3). Ligands for TLRs include both microbial and endogenous molecules, the latter group being particularly relevant to autoimmunity (see below). Microbial ligands include components of Gram-positive bacteria, Gram-negative bacteria, yeast, and protozoans. For example, lipoteichoic acid and fungal products (e.g., zymosan) signal through TLR-2, lipopolysaccharide activates TLR-4 signaling, dsRNA signals through TLR-3, flagellin through TLR-5, ssRNA through TLR-7 and TLR-8, bacterial or viral DNA through TLR-9, and *Toxoplasma* profilin through TLR-11.⁶ Although viral and bacterial nucleic acids are the most likely ligands for TLRs, accumulating data demonstrate that complexes containing endogenous nucleic acids are clearly able to signal through TLRs. Although the exact nature and source of endogenous ligands for TLRs *in vivo* remain unclear, recent studies have demonstrated that components from stressed, injured, and dying cells may play critical roles in this regard.³⁴

Working in several models, numerous investigators have now provided evidence that the targeting of frequently targeted nucleoprotein autoantigens (which contain DNA or RNA) results from the ability of these nucleic acid components to ligate TLRs. Early studies demonstrated that anti-chromatin immune complexes could activate dendritic cells through the cooperation of FcγR and TLR-9. Similarly, B cells could be activated by immune complexes that could serve as ligands for both FcγR and TLR-9. Similar results have been demonstrated for TLR-7 and RNA-containing immune complexes. While the *in vitro* data demonstrating that nucleic acid-containing autoantigens have the capacity to signal through TLRs is very clear, it was important to demonstrate that such signaling is of relevance *in vivo* to autoimmunity. Such data have recently been obtained in various *in vivo* studies using mice deficient in TLR-9 and/or TLR-7. For example, when TLR-9 deficiency is bred on to MRL-lpr mice, which are an excellent model of SLE, animals no longer get autoantibody responses to chromatin. Interestingly, these animals nevertheless manifest the SLE phenotype, in some cases, more severely than the TLR-9-sufficient animals.³³ In

another model, Ehlers et al. showed that TLR-9 deficiency both inhibits anti-DNA responses and also abrogates the development of renal disease.³⁵ Similarly, when mice are rendered TLR-7-deficient, the autoantibody response to Sm is markedly inhibited, and severity of the SLE phenotype is improved.³³ Thus, TLR-9 and TLR-7 deficiency appeared to have dramatic and different effects on clinical disease in lupus-prone mice.

These data confirm that autoantigens frequently selected in different autoimmune phenotypes likely have the dual property of being able to activate simultaneously the innate and adaptive immune systems, and that the ability to co-ligate TLRs plays a critical role. Whether other frequently targeted autoantigens in autoimmunity, which do not have nucleic acids as intrinsic components, can similarly ligate TLRs or innate immune receptors remains to be determined. Importantly, these approaches have underscored the significant complexity of the system, and the importance of defining the balance between signaling through different TLRs in integrating the overall outcome of exposure to various combinations of autoantigens.

The source, form, and uptake of nucleic acids appear to play a large role in determining adjuvant activity. For example, while bacterial and viral DNA, and oligonucleotides with CpG motifs have significant adjuvant activity,³⁶ mammalian genomic DNA, in which CpG is usually methylated, has very poor adjuvant activity. In contrast, human DNA present within immune complexes in SLE serum activates plasmacytoid dendritic cells effectively, in a DNA-dependent way. Several potential explanations have been advanced to explain these observations.⁶ First, that FcγR-mediated uptake effectively captures self-DNA bound by anti-DNA antibodies and directs it to the correct endosomal compartment for TLR signaling. Second, that co-ligation of TLR-9 and either B-cell receptor or FcγR alters the signaling threshold of immune complexes. Last, that the difference lies in the nucleic acid itself, with additional modifications of DNA and RNA structure occurring in cells under different physiologic circumstances (e.g., cell death) and regulating nucleic acid binding to TLRs.

The TLR–interferon interface has been recognized as critical in the propagation phase of systemic autoimmune diseases, and has been reviewed extensively.^{37, 38} Although it is likely that the TLR effects in autoimmunity are expressed in a wide variety of cell types, much attention has been focused on plasmacytoid dendritic cells, a relatively rare class of immature dendritic cell that can secrete large amounts of type I interferons upon TLR ligation, and that express TLR-7 and TLR-9 at high levels. Lovgren and colleagues recently demonstrated that, when added to material from apoptotic or necrotic cells, autoantibodies from SLE and Sjögren's syndrome patients with specificity for DNA or RNA autoantigens induce striking interferon secretion.³⁴ IFN-α-inducing activity is abrogated by chloroquine or bafilomycin, agents that interfere with endosome acidification and TLR-7 and TLR-9 signaling. Type I interferons have a broad set of functions that likely contribute to the feed-forward, propagation phase of systemic autoimmune diseases.^{6, 39} For example, they: (1) promote the differentiation of monocytes into mature dendritic cells, which drive autoreactive T- and B-cell responses; (2) increase target cell sensitivity to killing pathways; (3) upregulate cytotoxic effector pathways; and (4) upregulate expression of autoantigens like Ro52.

This general ability of autoantigens, particularly in the context of immune complexes, to stimulate interferon and other cytokine secretion, is likely a critical principle in the initiation and propagation of autoimmunity.

Enhanced autoantigen expression in the target tissue

The striking association of specific autoantibody responses with distinct phenotypes suggests that autoantigen expression or form in specific target tissues may play an important role in both focusing the immune response and generating tissue damage. Unfortunately, very little is currently known about such parameters *in vivo* in relevant target tissues, both in normal and pathologic circumstances. Recent studies on human autoimmune myopathies have begun to provide important insights into this problem. Thus, myositis-specific autoantigens are expressed at very low levels in control muscle, but at high levels in myositis tissue, where antigen expression is at highest levels in regenerating muscle cells.⁴⁰ Interestingly, histidyl tRNA synthetase expression (HRS antibodies are associated with autoimmune myopathies with interstitial lung disease) is also found at high levels in lung. These data suggest that enhanced autoantigen expression in the target tissue may be a feature of disease propagation, and that antigen expression during tissue repair may provide an ongoing antigen source to sustain and amplify tissue damage. Defining whether similar principles are operating in other autoimmune diseases, and elucidating the pathways of antigen expression in relevant target tissues, is an important focus of future studies, as the regulation of antigen expression (rather than exclusively pathways of immune-mediated damage) may have important therapeutic potential.

Systemic lupus erythematosus

Cynthia Aranow, Betty Diamond, Meggan Mackay*

51

Systemic lupus erythematosus (SLE) is a systemic autoimmune disease characterized by the production of autoantibodies and a diversity of clinical manifestations. It most commonly presents in women during their child-bearing years. Although the etiology of SLE is unknown, both genetic and environmental factors contribute to loss of self-tolerance. Current therapeutic modalities are anti-inflammatory and immunosuppressive.

■ EPIDEMIOLOGY ■

The American College of Rheumatology (ACR) classification¹ (Table 51.1) is the most widely accepted instrument for ‘diagnosing’ lupus; however, these criteria do not represent the full spectrum of disease. They were created to identify SLE patients for clinical studies. Patients fulfilling four out of the 11 criteria are classified with SLE with approximately 95% certainty, although many individuals who meet only two or three criteria are ‘diagnosed’ with SLE. During the child-bearing years, the ratio of women to men with lupus is approximately 9:1. This ratio is less in younger and older populations, supporting a role for hormonal factors in disease induction. The majority of lupus presents during adulthood and approximately 20% are diagnosed in the pediatric population.

Lupus occurs throughout the world; susceptibility is linked to ethnicity. Overall incidence rates reported during the last 25 years in North America vary from 2 to 7 per 100 000. Incidence rates in African-Americans, Afro-Caribbeans, Hispanics, and Asians are approximately three times greater. The prevalence in the USA ranges from 50 to 80 per 100 000. Clinical manifestations of disease are also modulated by ethnicity (Table 51.2).

■ IMMUNOPATHOGENESIS ■

The immune system is designed to protect the host against foreign pathogens without damaging self. To accomplish this, a complex system has evolved that treads a delicate balance between self-defense and autoreactivity. Clearly, with the universal production of autoantibodies and characteristic pathological findings of inflammation, vasculitis, vasculopathy,

and immune complex deposition, SLE patients display a failure to down-regulate autoreactivity. The heterogeneity of disease manifestations reflects the multiplicity of genetic, hormonal, and immune abnormalities contributing to clinical disease (Table 51.3). Progression from initial autoreactivity to clinical disease occurs over time (Fig. 51.1).

AUTOANTIBODIES

Most autoantibodies in lupus bind nuclear antigens, although some bind cell membrane antigens, plasma proteins, and extracellular matrix antigens. Antinuclear antibodies (ANA) are present in over 98% of patients diagnosed with SLE. Their presence is not specific to SLE as they are present in patients with other autoimmune diseases (e.g., rheumatoid arthritis, scleroderma, Sjögren’s disease), malignancies, infections including viral (hepatitis) and parasitic (malaria) as well as in response to environmental triggers such as therapeutic agents (see section on drug-induced lupus, below). Furthermore, ANA are found in low titer in 5% of the general population with prevalence increasing with age. In commercial laboratories ANA are typically detected by their binding to Hep-2 cells. Common ANA specificities found in lupus patients include dsDNA, ssDNA, extractable nuclear antigens (such as Sm RNP, Ro and La), histones, and chromatin. Specific ANA are associated with disease subsets such as anti-Ro antibodies with subacute cutaneous and neonatal SLE, and anti ds-DNA antibodies with renal disease. The titers of most autoantibodies do not correlate with disease activity; anti-dsDNA antibodies are a notable exception, fluctuating with disease activity, thereby suggesting a pathogenic role for this autoantibody in disease pathogenesis.

THE PREDISPOSED HOST: GENETIC CONTRIBUTIONS

SLE is a multigenic disease. Most disease-associated alleles are present in healthy individuals in the population. Only when these alleles are present in combination and interact with an appropriate environmental trigger will a lupus-like phenotype arise. The degree of familial disease clustering and the higher disease concordance in monozygotic versus dizygotic twins suggest

* Authors contributed equally and are listed in alphabetical order.

Table 51.1 American College of Rheumatology criteria for systemic lupus erythematosus

Criteria	Description
Malar rash	Fixed malar erythema, flat or raised
Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
Photosensitivity	Skin rash as an unusual reaction to sunlight, by patient history or physician observation
Oral ulcers	Oral and nasopharyngeal ulcers, usually painless, observed by physician
Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
Serositis	Pleuritis (convincing history of pleuritic pain or rub heard by physician or evidence of pleural effusion) or Pericarditis (documented by electrocardiogram or rub or evidence of pericardial effusion)
Renal disorder	Persistent proteinuria > 0.5 protein:creatinine ratio or > 3+ if quantification not performed or Cellular casts, may be red cell, hemoglobin, granular, tubular, or mixed
Neurologic disorder	Seizures—in the absence of offending drugs or known metabolic derangements, e.g., uremia, ketoacidosis, or electrolyte imbalance or Psychosis—in the absence of offending drugs or known metabolic derangements, e.g., uremia, ketoacidosis, or electrolyte imbalance
Hematologic disorder	Hemolytic anemia—with reticulocytosis or Leukopenia (< 4000/mm ³ total on two or more occasions) or Lymphopenia (< 1500/mm ³ on two or more occasions) or Thrombocytopenia (< 100 000/mm ³ in the absence of offending drugs)
Immunologic disorder	Anti-ds DNA: antibody to native DNA in abnormal titer or Anti-Sm: presence of antibody to Sm nuclear antigen or Positive finding of antiphospholipid antibodies based on: (1) an abnormal serum level of IgG or IgM anticardiolipin antibodies; (2) a positive test for lupus coagulant using a standard method; or (3) a false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by <i>Treponema pallidum</i> immobilization or fluorescent treponemal antibody absorption test
Antinuclear antibodies	An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with 'drug-induced lupus' syndrome

Ig, immunoglobulin.

both an underlying genetic susceptibility and the importance of environmental or epigenetic factors. Presumed susceptibility genes identified in humans include those affecting differentiation and survival of B cells, lymphocyte activation, proliferation and apoptosis, cytokine production, antigen presentation, and clearance of apoptotic debris. Many of these genes are also implicated in susceptibility to other autoimmune diseases (e.g., CTLA-4 in Graves disease and type 1 diabetes,² PTPN22 polymorphisms in rheumatoid arthritis and type 1 diabetes³). Candidate genes are evaluated individually for disease association by looking for different frequencies of specific gene polymorphisms between affected individuals and normal controls. Alternatively, in linkage studies genetic information is assessed statistically, looking for co-inheritance of specific polymorphisms associated with clinical disease in families with multiple affected members.

Genes associated with antigen presentation

Polymorphisms of major histocompatibility complex (MHC) genes determine the peptides of self antigens and microbial and foreign antigens presented within the MHC that select the naïve T-cell repertoire. Human leukocyte antigen (HLA) DR2 haplotypes in Afro-American, African, Taiwanese, and Korean populations and HLA DR3 haplotypes in Caucasian populations have been associated with a two- to threefold increased risk for developing SLE.⁴ Recent evidence demonstrating close associations between anti-Ro antibodies with HLA-DR3 and anti-La antibodies with HLA-DR25 is consistent with the concept of an antigen-driven process involving T-cell recognition.

Genes associated with impaired clearance of apoptotic debris

Patients with severe deficiencies of C2, C4, and C1q display disease risks of 10%, 75%, and 90% respectively for SLE.⁶ Reduced uptake of apoptotic cells has been implicated in disease initiation in murine models of SLE and is seen histopathologically in lymph nodes of lupus patients.⁷ Though homozygotes for null alleles of C2, C4, and C1q are at significantly increased risk, these genetic haplotypes are rare. Polymorphisms of mannose-binding lectin (MBL) and C-reactive protein (CRP), acute-phase reactants that facilitate opsonization and phagocytosis of immune complexes, apoptotic debris and microbes, associate with SLE susceptibility; MBL haplotypes appear to be more important in Chinese and Spanish populations than in Caucasians.

Genes associated with lymphocyte activation, proliferation, and function

The Fcγ receptors, FcγR1 (CD 64), FcγR2 (CD32), and FcγR3 (CD16), have different binding affinities for immunoglobulin G (IgG) and immune complexes, as well as different cell-specific expression and function. FcγR1, FcγR2a, and FcγR2b are all activating receptors. Cross-linking results in degranulation, phagocytosis, antibody-dependent cellular cytotoxicity, cytokine gene transcription, and release of inflammatory mediators. In contrast, FcγR3 is an inhibitory receptor. Cross-linking of FcγR3 and the B-cell receptor (BCR) results in decreased intracellular calcium flux and decreased B-cell activation and proliferation. Engagement of FcγR3 on dendritic cells also delivers an inhibitory signal. Deficiency in FcγR3 results in a lower threshold for B-cell activation and unopposed activating FcR signaling in dendritic cells and macrophages. Substitutions

of one or more amino acids in the activating FcγR genes—arginine (R) for histidine (H) at position 131 in FcγR2a and phenylalanine (F) for valine (V) at position 158 in FcγR3—results in functional polymorphisms of these FcγRs with decreased binding affinity for IgG immune complexes. Associations between the FcγR2a R131H allele and disease susceptibility or nephritis occur in Brazilian, Thai, Korean, German, and African-American populations. The recent finding that the FcγR2a R131H allele predicts the efficacy of rituximab-induced B-cell depletion in SLE patients suggests that FcR polymorphisms may also predict a therapeutic response.⁸ FcγR3a F158V and FcγR3b NA2/NA2 polymorphisms are reported to associate with disease susceptibility in Dutch, Korean, Thai, and Caucasian populations. The FcγR3b I232T allele leads to the inability of the receptor to enter lipid rafts and is associated with SLE in Asian populations.⁹ The collective results of these studies suggest substantial ethnic variation in these genetic polymorphisms.

CTLA-4 is upregulated on T cells after activation and dampens the inflammatory response. It has a higher affinity than CD28 for binding to B7.1 (CD80) and B7.2 (CD86), thereby competitively inhibiting engagement of CD28, and blocking the co-stimulatory signal required for activation. CTLA-4 ligation of B7 also activates indoleamine 2,3-dioxygenase (IDO) expression, an enzyme involved in tryptophan metabolism, and diminishes T-cell proliferation. Finally, CTLA-4 is critical for activation of regulatory T cells. In its absence, an uncontrolled, lethal inflammatory response occurs in mice. CTLA-4 alleles with decreased production of soluble CTLA4 are implicated in the pathogenesis of several autoimmune diseases, including Sjögren's disease, ulcerative colitis, psoriasis, type 1 diabetes, and multiple sclerosis, as well as SLE.²

The PTPN22 gene encodes a tyrosine phosphatase responsible for downregulating T-cell receptor activation. A polymorphism in PTPN22 resulting in diminished ability to control T-cell receptor activation has been reported in SLE. Similar to CTLA-4, the same polymorphism in PTPN22 is associated with other autoimmune diseases (rheumatoid arthritis, type 1 diabetes), suggesting a common mechanism of immune dysregulation in multiple autoimmune diseases.

Genes encoding cytokines and chemokines

Monocyte chemoattractant protein (MCP-1) is a potent chemoattractant for monocytes, memory T cells and natural killer T cells. MCP-1 expression is upregulated in renal tubular cells and glomeruli in lupus nephritis. Urinary levels of MCP-1 are increased in patients with active

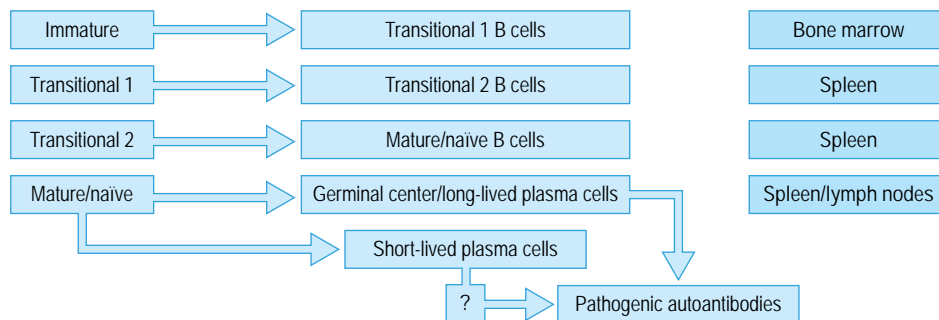

Fig. 51.1 Autoreactive B-cell checkpoints. There are tolerance checkpoints at every stage of B-cell activation and maturation. How many checkpoints need to be breached to achieve a pathogenic state and clinical disease is not known.

lupus nephritis. A functional MCP-1 polymorphism resulting in increased production of MCP-1 has been associated with SLE nephritis.¹⁰ Polymorphisms in the tyrosine kinase-2 (*tyk2*) gene are associated with increased expression of type I interferons (IFN- α , IFN- β) in SLE. IFN- α -regulated genes are highly expressed in peripheral blood cells from SLE patients compared to healthy controls (the interferon signature).¹¹ IFN- α mediates maturation of dendritic cells and monocytes, increasing the capacity for T-cell activation, and promotes B-cell differentiation and Ig class switching. However, in two murine models of lupus, decreases in type 1 interferons unexpectedly led to worsening disease, suggesting that the effect of IFN- α on autoimmunity is more complex than currently appreciated.

Multiple polymorphisms in the IL-10 gene have been reported, with conflicting results with respect to SLE susceptibility. A meta-analysis of 15 studies concluded that some IL-10 polymorphisms do associate with SLE but their importance is modulated by ethnic background.¹²

In the NZB/W murine model, a tumor necrosis factor (TNF) allele associated with low production is linked with disease, and treatment with TNF decreases autoantibody production. Consistent with this observation, TNF blockade for rheumatoid arthritis or inflammatory bowel disease leads to autoantibody production and infrequently to frank lupus. Several polymorphisms for genes encoding TNF- α and TNF- β (lymphotoxin- α) have been associated with SLE; these associations are also influenced by ethnicity.¹³

Genes associated with cell survival

Fas ligand (expressed on activated T cells) binding to Fas (CD95) stimulates a signaling pathway resulting in apoptotic death of the Fas-expressing cell. Fas-induced apoptosis of activated cells contributes to the elimination of autoreactive B and T lymphocytes. Lymphopenia in SLE has been associated with increased Fas expression on lymphocytes and Fas and Fas ligand alleles have been linked to disease susceptibility.¹⁴

Bcl-2 family genes encode intracellular proteins that are either pro- or anti-apoptotic. Increased expression of Bcl-2, an anti-apoptotic molecule, leads to a lupus-like serology and nephritis in mice with certain genetic backgrounds. Increased intracellular levels of Bcl-2 are reported in SLE. In Chinese and Mexican populations, Bcl-2 alleles are associated with increased risk of SLE. The combination of a Bcl-2 susceptibility allele and interleukin-10 (IL-10) susceptibility allele confers a 40-fold increased risk of SLE, demonstrating that *infelicitous* combinations potentiate risk.¹⁵

B CELLS

B-cell selection

Autoreactive B cells *per se* do not confer autoimmunity. The process of immunoglobulin variable region gene rearrangement produces large numbers of self-reactive B cells. To avoid autoimmunity, B cells displaying self-reactive immunoglobulin are deleted centrally in the bone marrow and at subsequent checkpoints in the periphery (Fig. 51.1). Several of these checkpoints appear deficient in SLE. Analysis of antibodies cloned from bone marrow-derived and peripheral blood B cells from healthy donors reveals that up to 75% of antibodies cloned from early immature B cells are autoreactive; 60% of these autoantibodies demonstrate an antinuclear staining pattern. The percent of autoreactive B cells decreases significantly as B cells progress through normal development. The first checkpoint occurs in the marrow at the immature B-cell stage,

where autoreactive B cells may undergo anergy, deletion, or receptor editing. Consequently, the frequency of autoreactive B-cell clones among newly minted B cells in the blood decreases to 40%. The frequency of autoreactive cells decreases further to 20% in the mature naïve B-cell population, although the mechanisms are not fully understood. The IgM cross-reactive autoantibodies made by these remaining autoreactive mature naïve B cells are thought to facilitate clearance of apoptotic cells, decreasing the development of potentially pathogenic T- and B-cell responses to self antigens.

Another important peripheral checkpoint is entry into the T-cell-dependent, long-lived memory compartment. Focusing on a population of B cells (9G4 B cells) that express antibodies encoded by the VH 4.34 gene reactive with *N*-acetyllactosamine (NAL) determinants of glycoproteins on blood group antigens targeted by cold agglutinins, gangliosides, gastrointestinal mucins, glycolipids, and CD45 on B lymphocytes, it is possible to track the fate of autoreactive peripheral B cells.¹⁶

9G4 B cells are present in 5–10% of the naïve B-cell population in healthy donors as well as in the IgM memory compartment. However, 9G4 B cells are excluded from the T-cell-dependent IgG memory and plasma cell populations, suggesting that these autoreactive cells fail to cross a developmental checkpoint following activation in normal individuals. Evaluation of tonsillar biopsies and spleens from healthy donors shows that the frequency of germinal centers with 9G4⁺ cells is less than 1%, implying that negative selection of autoreactive cells occurs at the transition of naïve to germinal center cells. In contrast to these findings from healthy donors, tonsillar biopsies from SLE patients demonstrate that 15–20% of germinal centers are positive for autoreactive 9G4 B cells. Autoreactive B cells surviving negative selection in the germinal center join the pool of long-lived antibody-producing plasma cells that home to the marrow. These cells tend to be refractory to treatment with cytotoxic drugs or anti-CD20 antibody.

Pathogenic B-cell autoimmunity

Autoantibodies characteristic of SLE are somatically mutated, IgG autoantibodies reflective of germinal center maturation. While studies demonstrate a failure to tolerize naïve autoreactive B cells, it is possible that some pathogenic autoantibodies are not derived from

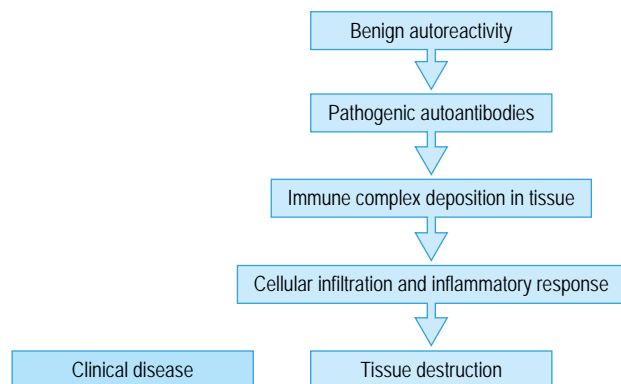

Fig. 51.2 Spectrum of autoimmunity.

natural autoantibodies, but are derived from an antibody with no autoreactive specificity. Support for this hypothesis includes the back mutation of a few anti-DNA antibodies to their germline-encoded precursors which lack autoreactivity. The failure of censoring mechanisms in germinal centers may reflect intrinsic B-cell abnormalities or abnormalities in co-stimulatory molecules, cytokines, dendritic cell, and T-cell interactions.

B-cell signaling

Hyperactive B-cell responses to immunologic stimulation are implicated in the production of pathogenic antibodies. SLE B cells have increased intracellular Ca^{2+} flux in response to BCR signaling.¹⁷ Increased intracellular Ca^{2+} flux in SLE B cells is attributed, in part, to $\text{Fc}\gamma\text{RIIb}$ dysfunction, including defective upregulation of $\text{Fc}\gamma\text{RIIb}$ on memory B cells, decreased availability of the $\text{Fc}\gamma\text{RIIb}$ -associated intracellular SHIP protein, and an $\text{Fc}\gamma\text{RIIb}$ polymorphism (Ile 232 Thr) that prevents partitioning of the receptor into lipid rafts where it usually associates with the BCR.⁹

The intracellular protein tyrosine kinase Lyn has both positive and negative effects on BCR signaling. Decreased expression of Lyn results in increased intracellular Ca^{2+} flux; B-cell hyperactivity is present in Lyn-deficient mice. Lyn expression is decreased in one-half to two-thirds of resting and activated B cells in SLE patients, suggesting that Lyn may modulate negative regulation of BCR signaling in human disease. A mutation in mice leading to increased expression of Lyn also results in an autoimmune phenotype with autoantibody production and severe glomerulonephritis.

B-cell rescue

B lymphocyte stimulator (BAFF; also known as BLyS) is a member of the TNF family and participates in B-cell maturation and survival. BAFF enhances survival of B cells through ligation of several receptors—BCMA, BAFF-R, and TACI. There is strong evidence supporting a role for BAFF in autoreactive B-cell rescue and SLE; mice overexpressing BAFF have a lupus-like disease.¹⁸ In humans BAFF is encoded in an SLE susceptibility locus and elevated serum levels of BAFF are reported in patients (although this may be secondary to the lymphopenia seen in SLE).

CD40/CD40 ligand (CD40L) interactions are essential for germinal center formation and differentiation of memory cells into plasma cells. The interaction between T cells expressing CD40L and B cells expressing CD40 results in B-cell proliferation. Immature autoreactive B cells can be rescued from antigen-induced apoptosis by engagement of CD40 or by IL-4.¹⁹ SLE T and B cells have upregulated CD40L, providing a critical molecule to mediate B-cell rescue.

B-cell pathogenicity unrelated to antibody production

An essential role for B cells in SLE that is independent of antibody production is demonstrated by the T-cell activation, kidney inflammation, and increased mortality in MRL/lpr lupus-prone mice that lack the ability to secrete antibody and their absence in mice that lack B cells. B cells are efficient antigen-presenting cells; B cells with self-reactive specificity that have escaped tolerance are likely to present self-peptides

to autoreactive T cells. These animal data are supported by initial observations of SLE patients treated with B-cell-depleting therapy demonstrating improvement in disease activity and normalization of B-cell compartments despite persistent elevation of serum autoantibody levels.

T CELLS

T cells in lupus contribute to the abrogation of self-tolerance by providing help to autoreactive B cells and facilitating the production of somatically mutated, high-affinity, pathogenic autoantibodies. Lupus T cells display increased expression of activation markers. Upon stimulation of the T-cell receptor (TCR), there is an abnormally increased intracellular influx of Ca^{2+} caused by a substitution of TCR ζ -chain for the γ -chain of the Fc receptor. Although there is a heightened Ca^{2+} influx after TCR stimulation, activation is impaired and IL-2 production is decreased. Lupus T cells are additionally less susceptible to activation-induced cell death.

Self-tolerance is maintained in part by the suppressive actions of regulatory T cells (Tregs). Studies of Tregs in patients with SLE have demonstrated reduced numbers of peripheral $\text{CD4}^+\text{CD25}^+$ cells in patients with active disease.²⁰

HORMONAL INFLUENCES

The most compelling evidence for the role of sex hormones in SLE is the fact that lupus affects women of child-bearing age. The female-to-male ratio is 2:1 prior to menarche, 8–9:1 in the fourth decade, and 2:1 after menopause. Numerous case reports and studies of disease flares correlating with pregnancy, menstruation, and use of oral contraceptives containing high doses of estrogen suggest a role for estrogen in disease activity. A significant correlation in SLE between plasma levels of estradiol and clinical disease activity and increased α hydroxylation of estrogen in SLE yielding the more active metabolite 16α -hydroxyestrone is also reported.²¹ No significant differences in levels of sex hormones (including estrogen, testosterone, prolactin) are noted in male SLE patients, suggesting that the development of SLE in females may be more closely related to sex hormones than in men. Randomized, controlled studies of estrogen in SLE suggest that the use of exogenous estrogen in patients with stable disease may be safe; however, a subset of patients appear to have an estrogen-sensitive disease. Mild to moderate flare rates were significantly increased in postmenopausal women treated with hormone replacement therapy.

Most of what we understand about hormonal modulation of B-cell development comes from mouse studies.¹⁹ Estrogen treatment of NZB/W and MRL/lpr mice or castration of male lupus-prone mice exacerbates disease whereas oophorectomy of females ameliorates disease. Treatment of lupus-prone mice with the selective estrogen receptor modulator tamoxifen also ameliorates disease.

Estrogen and prolactin promote the loss of B-cell tolerance in mice that are not genetically predisposed to spontaneous autoimmunity. In nonautoimmune BALB/c mice that are transgenic for the heavy chain of a nephritogenic anti-DNA antibody, DNA-reactive B cells are regulated by negative selection and serum titers of the transgene-encoded anti-DNA antibody are low. After exposure to estrogen (at doses similar to those present during follicular and luteal phases of the

CLINICAL PEARLS

- >> Systemic lupus erythematosus (SLE) is a systemic disease with the potential to affect any organ system
- >> The differential diagnosis of a lupus flare mandates consideration of infection, drug toxicities, or other etiologies
- >> In the absence of data from randomized trials, use of aggressive treatment must be balanced against associated toxicity
- >> SLE patients are at high risk of developing atherosclerotic disease, osteoporosis, malignancy, diabetes mellitus and hypertension (HTN); screening for and reduction of modifiable risk factors are essential
- >> Appropriate vaccinations are advisable

estrus cycle), there is a significant increase in serum titers of the transgene-encoded antibody and a selective expansion and maturation of transgene-bearing autoreactive cells into marginal-zone B cells. Several estrogen-responsive genes have been identified in B cells, including *cd22* and *shp-1*; both result in diminished B-cell responsiveness to BCR cross-linking and less stringent negative selection. *Bcl-2* is also upregulated by estrogen and known to facilitate escape of autoreactive B cells from tolerance mechanisms. Two intracellular estrogen receptors, *ERα* and *ERβ*, mediate the response to estrogen. Polymorphisms of the *ERα* gene are associated with age of disease onset and disease severity in some human SLE populations.

Elevated prolactin levels are reported in 20% of patients with SLE and increased prolactin exposure in lupus-prone mice exacerbates disease activity. While treatment of patients with bromocriptine yielded equivocal results, treatment of NZB/W lupus mice with bromocriptine results in improved survival. Transmembrane prolactin receptors are present on a variety of cells, including T and B cells. Similar to the findings with estrogen treatment, prolactin treatment of BALB/c mice transgenic for the nephritogenic anti-DNA heavy chain leads to the development of a lupus-like serologic profile. Prolactin treatment, however, results in an expansion of autoreactive B cells with a follicular phenotype. Upregulation of both *Bcl-2* and *CD40* on B cells and *CD40L* on T cells occurs in response to prolactin, identifying two pathways that may be involved in the prolactin-mediated rescue of autoreactive B cells.

CLINICAL MANIFESTATIONS

SYSTEMIC FEATURES

The most common features of lupus are constitutional and include fatigue (which may be severe), malaise, low-grade fever, anorexia, and lymphadenopathy. These symptoms may accompany other, more severe organ system manifestations of active disease or may occur alone. Although frequent, these symptoms are nonspecific and do not aid in making the diagnosis of SLE nor in distinguishing flare in individuals with known disease. Infection must be excluded in a patient who presents with constitutional symptoms. Symptoms of fatigue and malaise may also represent fibromyalgia, which co-occurs with SLE.²²

MUSCULOSKELETAL INVOLVEMENT

The musculoskeletal system is the most common organ system involved, affecting the joints, muscles, soft tissues, and bones. In approximately 50% of patients, joint pain is the presenting symptom.

Arthritis and arthralgia

The pattern of joint involvement is usually symmetric, affecting the small joints of the hands, wrists, and knees. Pain in the ankles, elbows, shoulders, or hips or monoarticular involvement is less typical. The duration of joint pain and stiffness is variable, with morning stiffness typically lasting only for several minutes. Frequently, the subjective complaints of pain are greater than the objective findings of warmth, swelling, and, occasionally, erythema. Lupus arthritis is characteristically nonerosive and nondeforming. Some lupus patients do develop a hand deformity with hypermobile joints secondary to tendon and ligamentous laxity (Jacoud's arthritis) (Fig. 51.3). Erosions are seen on plain radiographs in fewer than 5% of cases and patients with erosions are said to have 'rhumus,' which is typically associated with deforming arthritis, Sjögren's syndrome, subcutaneous nodules, and serologies that include a positive rheumatoid factor. Utilization of more sensitive imaging techniques such as magnetic resonance imaging (MRI) may show erosions in patients without deforming arthritis. Proliferative tenosynovitis, synovitis, and capsular swelling are other features of soft-tissue involvement that may be seen on MRI.

Joint effusions, when they occur, are usually small. The fluid is clear, yellow with normal viscosity, and able to form a mucin clot. It is typically noninflammatory with a normal glucose level and a white blood cell (WBC) count of less than 2000 cells/ml that is predominantly lymphocytic. Occasionally joint effusions are exudates, with leukocyte counts approaching 15,000 cells/ml and increased protein levels. ANA performed on the synovial fluid may be positive and LE cells may be present. Synovial fluid complement levels may be normal or depressed. Synovial histology in lupus is not specific and shows synovial hyperplasia with fibrin deposition and microvascular changes that include a perivascular infiltrate in the majority of cases.

Fig. 51.3 Jacoud's arthritis in systemic lupus erythematosus.

Tendinitis

Tendinitis is not usually attributed to SLE unless associated with tendon rupture. This is an uncommon feature of lupus but, when present, is usually located in the Achilles tendon or the tendons around the knee. Tendon ruptures are more common in males and have been associated with trauma, steroid use, and long disease duration.²² Biopsy shows a mononuclear infiltrate with tendon degeneration and neovascularization. The diagnosis can be easily demonstrated on MRI.

Myositis/myalgia

Generalized myalgia is extremely common in lupus. It frequently affects the deltoids and quadriceps and occurs during flares of active disease. Muscle disease secondary to treatment with corticosteroids, statins, and anti-malarials or in association with hypothyroidism is also frequent and must be considered in the evaluation of a lupus patient with myalgia. Inflammatory muscle disease with weakness and an elevated creatine phosphokinase is less common and occurs in approximately 10% of lupus patients.²² Electromyography may be normal or may be characteristic of the myositis observed in polymyositis or dermatomyositis. Muscle biopsy may also be normal or may show changes associated with dermatomyositis such as a perivascular or perifascicular infiltrate and immunoglobulin and complement deposition. Muscle atrophy, fiber necrosis, microtubular inclusions, and/or a mononuclear infiltrate have also been documented. MRI findings are nonspecific.

Avascular necrosis

Avascular necrosis (AVN) has been reported in up to 30% of lupus patients, and is frequently asymptomatic.²³ The most commonly affected site is the femoral head. Groin pain exacerbated with weight-bearing is a common complaint. In addition to the hip, AVN commonly involves the knees, shoulders, and wrists. The majority of AVN is associated with administration of high doses of corticosteroids (> 30 mg/day). Other reported risk factors include Raynaud's phenomenon, hyperlipidemia, and the presence of antiphospholipid antibodies, although these are unconfirmed. Bone biopsy in lupus patients affected by AVN does not reveal unique findings.

MUCOCUTANEOUS MANIFESTATIONS

Skin

The skin is also commonly affected in SLE with numerous types of lesions that are influenced by race and genetic factors as well as environmental exposures and age at onset of disease²⁴ (Table 51.3). Though rarely life-threatening, cutaneous lesions may be quite disfiguring.

Acute cutaneous SLE

The malar rash typically occurs across the cheeks and nose but may include the forehead and chin, sparing the nasolabial folds (unlike seborrheic dermatitis) (Fig. 51.4). It usually begins as small discrete erythematous macules or papules that coalesce and is frequently associated with sun exposure. Some patients additionally have facial swelling. The

malar rash heals without scarring. The differential diagnosis of a malar rash includes acne rosacea, seborrheic dermatitis, erysipelas, dermatomyositis, and contact dermatitis. Microscopic analysis reveals a sparse inflammatory lymphocytic dermatitis with occasional histiocytes engulfing nuclear debris resembling LE cells found close to the dermoepidermal junction. Immunofluorescent staining for complement components and immunoglobulin at the dermoepidermal junction is positive in 70–80% of patients with a malar rash.

Photosensitivity is common in SLE; many lupus rashes arise in sun-exposed areas and sun exposure can precipitate flares of systemic disease. Typically, a photosensitive rash erupts within hours of sun exposure and consists of tiny pruritic plaques and vesicles lasting several days. Ultraviolet (UV) light induces DNA damage and triggers apoptosis of keratinocytes. SLE patients have increased numbers of apoptotic keratinocytes after exposure to UV light,²⁵ thus sun exposure may provide a rich source of antigen. UV light and apoptosis have also been implicated in the translocation of nuclear antigens to surface blebs and with increased chemotaxis of plasmacytoid dendritic cells and T cells to skin lesions, with ensuing production of pro-inflammatory cytokines (IL-1, TNF- α , IL-10, IFN- γ). Of note, photosensitivity, along with oral ulcers, alopecia, and Raynaud's phenomenon, has been identified as a predictor of systemic involvement and more severe disease.

Subacute cutaneous lupus (SCLE) is characterized by recurrent, non-scarring, nonindurated skin lesions associated with anti-Ro antibodies. This distinctive rash consists of erythematous papules and plaques, with or without adherent pityriasisiform scale, that erupt on the extremities and trunk, usually sparing the head and neck. These lesions may take an annular polycyclic form with a hypopigmented central area and tiny vesicles at the active margins and can be mistaken for erythema multiforme. The differential diagnosis also includes psoriasis, polymorphic light eruption, and tinea corporis. SCLE is exacerbated by UV light and a growing list of medications; common offenders are thiazides and calcium channel blockers (particularly in the elderly). Biopsy reveals a significant lymphocytic dermatitis confined to the superficial and mid dermis, frequently with associated dermal edema, mucinosis, and

Fig. 51.4 Malar rash in a systemic lupus erythematosus patient.

degenerating keratinocytes. Both TNF- α and IL-6 have been demonstrated in active SCLE lesions. SCLE is most commonly seen in Caucasian populations. Genetic analyses have revealed associations with HLA-A1, B8, and DR3 haplotypes, as well as with deficiencies of C2, C4, and C1q. Sixty to 90% of SCLE patients have anti-Ro antibodies while approximately 50% meet ACR criteria for SLE; only ~10% experience severe, life-threatening internal organ involvement.

Chronic cutaneous SLE

Discoid lesions (DLE) are usually localized to the head and neck in photoexposed areas with a predilection for the ears and periorbital areas (Fig. 51.5). DLE lesions range in diameter from a few millimeters to 10 cm. Early lesions appear as erythematous plaques with or without follicular hyperkeratosis, plugging, and scale and progress to scarring annular lesions with an erythematous, indurated border, adherent scale, and a central area with atrophy and telangiectasias. There are no autoantibody associations with DLE and only 5% of patients with DLE develop systemic lupus. High-titer ANA, Raynaud's phenomenon, and the presence of arthralgias may identify patients at risk for systemic evolution. Histopathology characteristically reveals a lymphocytic interface dermatitis with CD4 lymphocytes and plasmacytoid dendritic cells involving follicles and epidermis. There is vacuolar degeneration of the basal layer of epidermal keratinocytes and prominent keratotic follicular plugging. Dermal mucin deposition is also characteristic of DLE lesions and there is usually dense granular deposition of immunoglobulin (predominantly IgG) and C3 at the dermal-epidermal junction. Patients with C2, C4, and C1q deficiencies may be predisposed to DLE and polymorphisms in the promoter regions of genes associated with high IL-10 and low TNF- α are risk factors for DLE.

Lupus profundus typically presents as firm, tender, deep subcutaneous nodules that may atrophy over time. Overlying epidermal changes include DLE, ulcerations, and dystrophic calcification. Biopsy reveals a lobular panniculitis with patchy lymphoplasmacytic infiltrate in subcutaneous fat lobules. Panniculitis occurs in 10–20% of patients and must

be differentiated from a subcutaneous T-cell lymphoma or other variants of panniculitis such as erythema nodosum, pancreatic panniculitis, and morphea.

Nonspecific skin lesions reported in SLE are typically seen during disease flares and are associated with greater disease severity. These lesions include, but are not limited to, entities such as cutaneous vasculitis (Fig. 51.6), urticaria, Raynaud's phenomenon, livedo reticularis, alopecia, sclerodactyly, calcinosis cutis, atrophie blanche, bullous lesions, erythema multiforme, and leg ulcers.

The lupus band test (LBT) refers to the deposition of immunoglobulin (IgG, IgM, and/or IgA) and/or C3 along the dermoepidermal junction. Approximately 25% of normal individuals display weak IgM staining at the dermoepidermal junction; 70–80% of SLE patients have a positive LBT in sunexposed, nonlesional skin. Half of SLE patients have a positive LBT in non-sun-exposed, nonlesional skin. It is unclear if the LBT is a consequence of circulating ANA targeting denatured DNA from UV light-damaged keratinocytes, or immune complex deposition or anti-basement membrane antibodies. The test may be useful diagnostically and prognostically as it correlates with increased systemic disease severity.

In summary, the acute cutaneous lesions of malar rash and photosensitivity are strongly associated with systemic disease, whereas 50% of those with SCLE and only 5% of patients with DLE develop systemic disease. Conversely, the incidence of DLE lesions in lupus cohorts is variable (with one report of 73%) and the incidence of SCLE is approximately 5–10%. Nonspecific cutaneous lesions such as cutaneous vasculitis or ulcers are associated with a more aggressive disease course than most of the SLE-specific lesions.

Hair and nail

Hair involvement in SLE includes scarring alopecia resulting in permanent hair loss, induced by DLE. This can be differentiated from other common forms of scarring alopecia by immunofluorescent studies. Patchy or diffuse nonscarring alopecia is frequently associated with disease activity. Histologically, there is a peribulbar lymphocytic infiltrate surrounding shrunken anagen hair bulbs similar to findings in alopecia areata. The diagnosis is made by the presence of other criteria

Fig. 51.5 Discoid lesion in systemic lupus erythematosus.

Fig. 51.6 Cutaneous vasculitis affecting the hands in a patient with active systemic lupus erythematosus.

for SLE. Nonscarring alopecia resolves with complete hair regrowth with control of disease activity.

A wide spectrum of nail abnormalities, including pitting, ridging, onycholysis, and dyschromia with blue or black hyperpigmentation, are reported in up to 30% of SLE patients. Nailfold erythema with ragged cuticles and splinter hemorrhages resembling the changes seen in dermatomyositis are common. However, other than rare DLE lesions involving the nailbed, none are lupus-specific.

Oral lesions

The spectrum of oral lesions reported in SLE includes cheilitis, ulcerations, erythematous patches, lichen planus-type plaques on the buccal mucosa and palate, and DLE.²⁶ Most oral lesions are asymptomatic and must be looked for on exam. Positive immunofluorescent staining on biopsy may be useful to differentiate DLE from lichen planus-like lesions and leukoplakia. Lupus mucosal ulcerations demonstrate an interface mucositis and not leukocytoclastic vasculitis, as previously postulated. The incidence of mucosal lesions is variable depending on ethnicity (Table 51.3).

GASTROINTESTINAL MANIFESTATIONS

Gastrointestinal manifestations of SLE²⁷ are common; it is often difficult to differentiate between disease activity, side effects of medications, and infectious complications. Most SLE patients require therapy with nonsteroidal anti-inflammatory drugs and/or corticosteroids, increasing the risk of ulcer disease.

Esophagus

The prevalence of esophageal involvement varies. Many of the reviews citing a high incidence of dysphagia and odynophagia predate the advent of proton pump inhibitors and H₂ blockers and the relationship of medication use to symptoms is not clear. Dysphagia and heartburn are reported in 1–50% of patients, although dysmotility documented by decreased esophageal peristalsis and decreased lower esophageal sphincter pressure is observed in up to 72%. An inflammatory process involving esophageal muscle or vasculitic damage to the Auerbach plexus is thought to contribute to the esophageal dysmotility. Ulceration is rarely seen outside the context of infections such as invasive candidiasis, herpes simplex, or cytomegalovirus. SLE patients with a secondary Sjögren's syndrome may have salivary gland dysfunction resulting in decreased saliva contributing to dysphagia.

Abdominal pain/vasculitis

Abdominal pain is commonly seen in SLE with an incidence reported as high as 40%; the clinical challenge is to distinguish active SLE (serositis, pancreatitis, intestinal ischemia/vasculitis) from one of the long list of infectious, metabolic, vascular, mechanical, embolic, and medication-induced causes of abdominal pain.

The most catastrophic gastrointestinal disturbances are related to ischemia of the small and large intestines resulting from medium- and small-vessel vasculitis or thrombotic complications of anti-phospholipid antibodies. The mortality associated with intestinal ischemia is high. In

a review of 51 cases of SLE patients presenting with acute abdominal pain, a significant correlation between SLEDAI scores reflecting disease activity and intestinal ischemia due to vasculitis was found. Alternatively, the presence of a livedoid rash with thrombocytopenia and elevated antiphospholipid antibodies may suggest a thrombosis-related ischemia. Heme-positive stool, an elevated WBC count, and presence of an anion gap acidosis are indicative of perforation. Computed tomography (CT) of the abdomen is the preferred imaging test for evaluation of abdominal pathology. Bowel ischemia is suggested by wall thickening and edema, demonstration of the target sign in the bowel wall, dilatation of intestinal segments, engorgement of mesenteric vessels, and increased attenuation of mesenteric fat. Plain radiographs are useful for detecting free air from a perforated viscus. MR angiography is of limited use due to its decreased sensitivity for small-sized vessels.

Intestinal vasculitis has a reported prevalence of 0.2–53%. Its presentation is not necessarily severe abdominal pain; an insidious, stuttering course, with nausea, vomiting, bloating, diarrhea, post-prandial fullness, anorexia, and weight loss is well recognized. Mesenteric vasculitis preferentially affects the superior mesenteric artery, involving the small intestine more commonly than the large bowel. Vasculitis may occur in the esophagus, stomach, peritoneum, rectum, gallbladder, pancreas, and liver. In cases with an insidious clinical course, endoscopy and colonoscopy may provide evidence of ischemia demonstrating ulcerating or heaped-up lesions and overt vasculitis on biopsy. The lesions are segmental and focal. Histologically, there is a small-vessel arteritis and venulitis with neutrophilic, lymphocytic, and macrophage infiltrates and fibrinoid necrosis of the vessel walls, associated thrombosis, and mononuclear infiltrate in the lamina propria. There may be immunoglobulin, C3, and fibrin deposition in the adventitia and media.

Treatment of acute abdominal pain in SLE is tailored to the underlying cause. Given the potential consequences of undertreating intestinal vasculitis, most patients are treated with high-dose intravenous corticosteroids (1–2 mg/kg per day) and observed closely for progression of disease. Delayed surgical intervention in the event of necrotic bowel is associated with a poorer outcome. Most patients respond after treatment with corticosteroids; the decision to add other immunosuppressive agents is based on anecdotal evidence. There are no randomized trials of immunosuppressive agents to date for the treatment of intestinal vasculitis.

Peritonitis

Inflammation of serosal membranes is well described in SLE; despite evidence of peritoneal inflammation in 63% of autopsy studies, clinical pericarditis and pleuritis occur far more commonly than peritonitis. Acute peritonitis is attributed to peritoneal vasculitis or ischemia and presents with abdominal pain (see above). The finding of ascitic fluid by CT scan or ultrasound mandates an evaluation of the fluid to exclude an infectious etiology. Rarely, ascites may be attributable to hepatic or portal vein thrombosis. Chronic peritonitis characterized by large amounts of painless ascites attributable to SLE and not to heart failure, constrictive pericarditis or severe hypoalbuminemia due to nephrotic syndrome, liver disease, or a protein-losing enteropathy is rare. In lupus peritonitis, the ascitic fluid is generally exudative with a predominance of lymphocytes; LE cells, autoantibodies and low complement levels are frequent. Exclusion of malignancy and indolent infection (tuberculosis, fungal infections) is essential. On biopsy, the peritoneum is usually edematous, and sometimes hemorrhagic with lymphocytic perivascular infiltrates.

Pancreatitis

Pancreatitis attributable to SLE is rare, with an annual reported incidence of 0.4–1/1000. In a recent review of 77 reported cases, most patients with pancreatitis had evidence of other clinical or serological manifestations of disease.²⁸ Although corticosteroids and azathioprine are medications known to trigger pancreatitis, 34% of reported cases are not on these medications at the onset of pancreatitis and most patients respond to steroid therapy. The clinical presentation of pancreatitis is similar in patients with and without SLE: abdominal pain, nausea/vomiting, fever, and pain radiating to the back. In 97% of cases, the diagnosis is made based on elevated levels of amylase or lipase. CT and ultrasound as well as endoscopic retrograde cholangiopancreatography are useful, but less sensitive, diagnostic tools. Leukopenia, thrombocytopenia, and anemia are commonly observed. Histologic findings show inflammation and necrosis; there is a single report of pancreatic vasculitis. Mortality rates are reported from 18% to 27%; poor outcome is associated with increased systemic SLE activity (particularly low complement and thrombocytopenia) and the development of complications of pancreatitis. Patients receiving steroid therapy tend to have a better outcome.

Liver

Controversy continues over the existence of “lupoid hepatitis.”²⁹ Analysis of SLE livers from 52 autopsies in Japan revealed a variety of findings, including congestion (40/52), fatty liver (38/52), arteritis (11/52), cholestasis (9/52), and a few cases each of chronic persistent hepatitis, nodular regenerative hyperplasia, hemangioma, and cholangiolitis. Cirrhosis is an extremely rare complication of liver involvement in SLE. The distinction between subclinical liver inflammation related to SLE (lupus hepatitis/LH) and autoimmune hepatitis (AIH) is important since therapy and prognosis are different. In contrast to the mild enzyme abnormalities associated with lupus hepatitis, AIH is a progressive disease frequently leading to hepatic failure. Both conditions share a predilection for young women and both demonstrate features of autoimmunity, including hypergammaglobulinemia, arthralgias, and serum autoantibodies. Histologically, biopsies of LH reveal lobular and periportal lymphocytic infiltrates, in contrast to the periportal and piecemeal necrosis with dense lymphocytic infiltrates seen in AIH with progression to panlobular or multilobular necrosis and cirrhosis. Serologically, anti-ribosomal P antibodies are associated with liver disease in LH but not AIH; AIH is associated with antibodies to liver and kidney microsomes. Anti-smooth-muscle antibodies are observed in 60–80% of patients with AIH compared to 30% of patients with LH. Although both have a favorable response to steroids, AIH usually requires additional immunosuppressive agents.

Distinguishing LH from hepatitis C (HCV) can be difficult. Up to 30% of patients chronically infected with HCV have low titers of ANA and other autoantibodies (anti-DNA, anti-cardiolipin antibodies, and rheumatoid factor). They may also have cryoglobulins and associated cryoglobulinemic vasculitis. It is necessary to confirm a positive enzyme-linked immunosorbent assay (ELISA) for HCV with polymerase chain reaction (PCR) in patients presenting with arthritis, cutaneous vasculitis, and a positive ANA as SLE patients may have false-positive serological tests for HCV.

Protein-losing enteropathy

Profound hypoalbuminemia in the absence of severe nephrotic syndrome, liver disease, or constrictive pericarditis should trigger a consideration of protein-losing enteropathy (PLE). The diagnosis is confirmed with an increased α_1 -antitrypsin level in a 24-hour stool collection. A review of the 31 cases reported prior to 2002 found that only half the patients experienced diarrhea; endoscopy was either normal or revealed edematous bowel.³⁰ In biopsies from 22 patients, normal or edematous villi were seen in 12 patients, lymphangiectasia in two, dilated lymphatic vessels in two, inflammation in two, and venulitis in one. These biopsy results implicate a potential role of TNF- α and IFN- γ in the increased vascular and enterocyte permeability in PLE.

PULMONARY INVOLVEMENT

Lupus affects the lungs in diverse ways involving the pleura, lung parenchyma, and blood vessels. The most frequent and important complicating feature is infection, which must be considered before attributing a respiratory symptom to SLE.

Pleuritis

Pleuritis is the most common pulmonary manifestation of SLE, reported in 40–56%.³¹ Pleural involvement in up to 93% of lupus patients at autopsy suggests that much pleuritis may be asymptomatic. Clinically, patients note typical pleuritic pain. On physical exam, the most frequent abnormality is tachypnea; a pleural friction rub is present in some cases and pleural effusions occur in more severe cases. Pleural fluid is usually exudative with normal glucose and pH and elevated protein levels. The leukocyte count is variable and may range from several hundred to 20 000 cells/mm³; both a lymphocytic and neutrophilic predominance are reported. Immunologic testing on pleural fluid may show reduced complement levels and the presence of ANA, anti-DNA antibodies, and LE cells. Although these tests are commonly obtained, these results are neither sensitive nor specific to diagnose lupus pleuritis.

Lupus pneumonitis

Lupus pneumonitis is uncommon, occurring in up to 10% of patients. Patients present with dyspnea, cough, mild pleuritic chest pain, and fever. Pulmonary infiltrates are present on plain radiograph or CT. This presentation must be distinguished from an infectious etiology with

KEY CONCEPTS

- >> Continued heightened awareness of SLE to shorten the time between onset of symptoms and diagnosis will improve outcomes
- >> Lupus is a disease characterized by recurrent flares
- >> Attentive monitoring, even during periods of disease remission, leads to early recognition of impending flare, better control, and better prognosis
- >> Lupus is a chronic disease; the importance of emotional/social support and patient education cannot be overemphasized

appropriate cultures. Histologic examination of affected lung tissue shows alveolar edema and hemorrhage with hyaline membrane formation; immunofluorescent staining reveals immune complex deposition.

Pulmonary hemorrhage

Pulmonary hemorrhage is a rare but potentially fatal complication of SLE. Typically, symptoms include shortness of breath and hemoptysis or a cough productive of blood-tinged sputum accompanied by a fall in hemoglobin, usually occurring in the context of multiorgan involvement from SLE. Imaging may show patchy infiltrates. Lung function is marked by an increased diffusion capacity of the lung for carbon monoxide (DLCO) (secondary to alveolar blood). Histopathology shows bland intra-alveolar hemorrhage and hemosiderin-laden macrophages, although microangiitis with an inflammatory infiltrate and necrosis of the alveolar septa can occur. As hemorrhage into the lung may be secondary to thrombotic thrombocytopenia, demonstration of an inflammatory process in the pulmonary vessels or tissue is helpful to establish a diagnosis of primary pulmonary hemorrhage.

Chronic diffuse interstitial lung disease

Chronic diffuse interstitial lung disease is a relatively uncommon manifestation of SLE. Patients with anti-Ro antibodies may be at increased risk. It usually has a progressive course with a chronic nonproductive cough with dyspnea and pleuritic chest pains. Physical exam is frequently remarkable for basilar rales with diminished diaphragmatic movement. Pulmonary function tests demonstrate a restrictive pattern with decreased diffusion capacity; oxygen saturation is decreased. Imaging often shows interstitial fibrosis that is more prominent at the lung bases. High-resolution CT (HRCT) is a sensitive technique used for detection of parenchymal abnormalities. A recent study reported that 38% of lupus patients without known pulmonary involvement and normal chest radiographs had abnormal HRCT scans with reduced DLCO on pulmonary function testing. HRCT is also useful to determine the extent of treatable disease, i.e., fibrosis (honeycombing) versus inflammation (ground glass). The most reliable method to assess the extent of pulmonary inflammation in comparison to fibrotic damage is by histologic examination. Evaluation of bronchial alveolar lavage fluid helps to exclude infection.

Pulmonary hypertension

Pulmonary hypertension unrelated to chronic pulmonary emboli or interstitial lung disease occurs in SLE. Severe cases are rare; the recent recognition of milder cases may be partially attributed to the availability of newer effective therapies. Patients note progressive dyspnea commonly occurring in the absence of infiltrates on chest radiographs or significant hypoxemia. Chest pain and a chronic nonproductive cough are also frequently present. Pulmonary function testing reveals a reduced DLCO. Elevated pulmonary artery pressure is documented with cardiac angiogram or echocardiogram. Biopsy or autopsy specimens of the lung reveal 'plexiform' lesions that resemble those seen in primary pulmonary hypertension.

Shrinking-lung syndrome

The shrinking-lung syndrome refers to the rare findings of shortness of breath occurring in the absence of pleuritis or interstitial lung disease plus a chest X-ray showing elevated hemidiaphragms. Pulmonary

function testing shows a restrictive pattern with loss of lung volume. It is generally accepted that this syndrome results from diaphragmatic weakness (from a myopathic process) or chest wall restriction. There is no definitive therapy, although immunosuppressive therapy with cytotoxic agents usually results in an improvement of lung function and respiratory symptoms.

CARDIAC INVOLVEMENT

There are a number of ways in which lupus affects the cardiovascular system. The myocardium, valves, pericardium, and vessels can be affected.

Myocardium

Myocardial dysfunction in SLE is likely to be secondary to factors other than lupus, including hypertension, medications, or coronary artery disease (CAD). However, a cardiomyopathy resulting from immune-mediated myocardial inflammation does occur, either in isolation or concomitant with systemic disease, including myositis. Inflammatory myocarditis is often associated with anti-RNP antibodies. Histopathology typically shows a mononuclear, inflammatory cell infiltrate. Perivascular or myocardial wall deposits of immune complexes and complement have been demonstrated. Myocardial biopsy is useful for diagnosis as well as for determination of the extent of active inflammatory disease and fibrosis. Symptoms and signs of myocarditis include unexplained tachycardia, an abnormal electrocardiogram (with ST and T-wave abnormalities), cardiomegaly; and heart failure. Echocardiography may show systolic and diastolic ventricular dysfunction. Myocardial involvement without overt clinical signs occurs commonly and may be documented using Doppler echocardiography. A noninflammatory cardiomyopathy may be seen in association with high-dose cyclophosphamide, usually of the magnitude used to treat malignancy. This potential complication of therapy may become increasingly concerning as patients are exposed to greater cumulative doses of cyclophosphamide over time, or to doses of cyclophosphamide that are used in immunoablation protocols.

Valvular heart disease

Valvular abnormalities, with thickening, regurgitation, or verrucous vegetations, occur commonly in SLE and are documented by transesophageal echocardiography in 50–60% of patients.³² The characteristic Libman–Sacks lesion, nonbacterial verrucous vegetations, is observed at autopsy in 15–60% of patients. Mitral, aortic, and tricuspid valves are most frequently involved. Clinically these lesions are usually asymptomatic and hemodynamic compromise, rupture of the chordae tendinae, or infection are rare events. On histologic examination, mononuclear cells, hematoxylin bodies, fibrin and platelet thrombi, and immune complexes are present. Anti-phospholipid antibodies may be associated with the development of valvular heart disease, although their pathogenic role is still unproven.

Pericarditis

Serosal inflammation of the pericardium is a frequent manifestation of SLE. While asymptomatic pericarditis is common, occurring in greater than 50% of patients, clinical pericarditis is seen in only 25% of patients. Pericardial fluid and thickening can be detected by

echocardiography; cardiac silhouette enlargement on plain films is seen in the presence of large effusions. There are no unique signs and symptoms of pericarditis in lupus patients. Cardiac tamponade and constrictive pericarditis are infrequent. The histologic findings of acute pericarditis in lupus are inflammation with a mononuclear cell infiltrate accompanied by immunoglobulin and complement deposition. The pericardial fluid is usually an exudate with elevated protein concentrations, normal or low glucose levels, and an elevated WBC count that is primarily neutrophilic. Complement levels in the fluid are low and autoantibodies (ANA, dsDNA) and LE cells have been reported. Analogous to pleural fluid, results of pericardial fluid analysis are neither sensitive nor specific.

Coronary artery disease

Myocardial infarction, angina, and sudden death resulting from CAD are well described in SLE. Estimates of the prevalence of CAD vary widely; however, the risk of myocardial infarction is 50-fold greater in young women with lupus than in normal age-matched controls.³³ Coronary artery vasculitis is a potential cause of CAD but is exceedingly rare and surgical and postmortem specimens commonly show atherosclerotic plaque. The underlying mechanisms that result in accelerated atherosclerosis are unknown. The prevalence of traditional risk factors for CAD, such as hypertension, diabetes, and hyperlipidemia, is increased in lupus patients. However, lupus *per se* confers an additional increased risk for CAD. Lupus-related factors that have been reported include duration of SLE, duration of corticosteroid use, and absence of use of hydroxychloroquine. The potential contributing influence of antibodies to phospholipids or disease activity continues to be explored. There is a growing body of evidence supporting a risk conferred by inflammation *per se*. Patients with rheumatoid arthritis are recognized to have an increased risk of atherosclerotic events; increased atherosclerosis has also been reported in patients with systemic vasculitis. The pathogenic link between accelerated atherosclerosis and autoimmune inflammatory disease is not known; however, atherosclerosis involves more than the accumulation of lipid in an arterial wall. The atherosclerotic plaque is infiltrated by activated monocytes, macrophages, and T cells and expression of proinflammatory cytokines. If endothelial dysfunction and vascular injury are the events triggering atherosclerosis, there are multiple potentially responsible processes in lupus, including autoantibodies directed to endothelial cells, immune complexes, and enhanced cleavage of membrane endothelial protein C receptor.³⁴

RENAL INVOLVEMENT

Lupus nephritis is a common manifestation of disease with significant impact on morbidity and mortality. The prevalence of nephritis ranges from 50% to 75% in reported cohorts. Renal disease is more prevalent and more aggressive in Afro-Americans and Hispanics, who exhibit a greater incidence of proliferative nephritis than Caucasians. Low socioeconomic status, independent of ethnicity, is predictive of poor prognosis. Additionally pediatric lupus and male lupus are both associated with a greater incidence of, and more aggressive, nephritis. Onset of nephritis occurs at any time and monitoring for potential renal activity is an ongoing obligation. Clinically, patients are asymptomatic unless they are nephrotic or have developed end-stage renal disease. Renal disease is usually detected by abnormalities seen on examination of the urine, although a rising

creatinine or hypertension may herald renal involvement. The development of proteinuria on urinalysis or the presence of hematuria (> 5 red blood cells (RBCs)/high-power field) or pyuria (> 5 WBCs/high-power field) in the absence of other etiologies should prompt an evaluation for nephritis. Although not sought routinely in commercial laboratories, dysmorphic RBCs indicate a glomerular or tubulointerstitial source of the RBCs rather than the bladder. A 24-hour urine collection remains the most accurate measurement of urinary protein loss; however the protein/creatinine ratio in a spot urine is useful for following a patient with existing proteinuria. Monitoring serum creatinine as a surrogate for the glomerular filtration rate is a component of standard patient care; however, creatinine is an insensitive marker of lupus renal disease and should be used in conjunction with other assays. Renal activity is usually preceded or accompanied by serologic activity. Antibodies to dsDNA are almost always elevated or rising whereas measurements of serum complement (C3, C4, or CH₅₀) are usually low or dropping.

The World Health Organization (WHO) classification of lupus nephritis was recently modified by the International Society of Nephrology/Renal Pathology Society (ISN/RPS).³⁵ In general, membranous nephritis (class V) presents with a bland urinary sediment (i.e., no RBCs, WBCs or casts), nephritic-range proteinuria, a normal to mildly elevated creatinine, a normal blood pressure, normal complement components, and without anti-dsDNA. Patients with mesangial disease (class II) present with a bland or minimally active sediment, low-grade proteinuria (less than 500 mg/24 hours) and a normal serologic profile. Class III (focal) and class IV (diffuse) proliferative nephritis are characterized by an active urinary sediment, proteinuria, active serologies, and frequently with hypertension and elevated serum creatinine. Class III is defined as ≤50% glomerular involvement and class IV is defined as >50%. The extent of proteinuria, urinary sediment activity, serologic abnormalities, and creatinine elevation is often less in class III than in class IV renal disease. Most cases of class II nephritis do not require initiation of cytotoxic therapy and the renal prognosis (i.e., lack of progression to end-stage renal disease) is good. The prognosis of class III disease is dependent upon the degree of activity. Patients with greater activity, i.e., 40–50% of glomerular involvement, have a prognosis similar to that of patients with class IV disease. In addition to high-dose corticosteroid therapy, cytotoxic therapy is usually required to induce a clinical response in patients with class III or IV disease. Even with potent immunosuppressant therapy such as cyclophosphamide or mycophenolate mofetil, a partial or complete response is induced in only about 80% of patients. Relapses and flares of renal disease are not infrequent, particularly when tapering corticosteroids or discontinuing immunosuppressive treatment.

HEMATOLOGIC

Hemocytopenias occur frequently in SLE. Severity is influenced by gender and ethnicity (Table 51.4). Though the sensitivity of any cytopenia for diagnosing SLE is low (18–46%), the specificity is high (89–98%).³⁶ Evaluation for medication effects is essential before attributing a cytopenia to an immune-mediated mechanism.

Anemia

Antibody-mediated peripheral destruction of red blood cells, autoimmune hemolytic anemia (AHA), occurs in 5–14% of SLE patients (Table 51.4). The anti-erythrocyte antibody is usually an opsonizing IgG. The

specificities of the anti-erythrocyte antibodies in SLE have not been clearly defined; the only nonrhesus-specific antigen reported in SLE is the membrane band 3 anion transporter protein. The presence of AHA is associated with increased disease severity and decreased survival and is readily diagnosed by a positive Coombs test, elevated lactate dehydrogenase and total bilirubin, and the presence of spherocytes on the peripheral smear. There are also reports of an association between AHA and anti-phospholipid antibodies, which may reflect cross-reactivity with erythrocyte membrane antigens.³⁷

Anemia of chronic disease is the most common cause of anemia in SLE. The inhibitory effects of pro-inflammatory cytokines on erythrocyte production may be compounded by an inadequate erythropoietin response. Low erythropoietin levels in SLE may be attributable to renal disease as well as anti-erythropoietin antibodies. Although hemophagocytosis of hematopoietic cells is frequently noted on bone marrow biopsies, the hemophagocytic syndrome characterized by spiking fevers, tender hepatosplenomegaly, anemia, leukopenia, and markedly elevated serum ferritin is rare.

Lupus is also associated with a thrombotic microangiopathic hemolytic anemia with schistocytes, helmet cells, and triangular fragments of red blood cells. The clinical constellation of high fever, renal insufficiency, neurologic symptoms, and thrombocytopenia is characteristic of thrombotic thrombocytopenic purpura (TTP). Coexistent TTP and SLE is a rare and frequently fatal phenomenon, with fewer than 50 reported cases; its pathogenesis is unclear. Antibodies to ADAMTS 13 (von Willebrand factor cleaving protease) have been found in some SLE patients;³⁸ up to 50% of SLE patients with coexistent TTP have anti-phospholipid antibodies.

Leukopenia

Leukopenia, either neutropenia or lymphopenia, occurs in 15–50% of patients (Table 51.4). Both neutropenia and lymphopenia may reflect disease activity and predispose to infection. Anti-neutrophil antibodies directed against membrane components of mature and progenitor cells

are implicated in neutropenia; Western blot analysis of target antigens reveals several bands, including a 60-kDa band that shares sequence with the 60-kDa Ro antigen. Functional consequences of these anti-neutrophil antibodies include decreased phagocytosis and accelerated apoptosis. Antibodies against granulocyte colony-stimulating factor (G-CSF) and hyposensitivity of myeloid cells to G-CSF also contribute to SLE neutropenia. Binding of TNF-related apoptosis-inducing ligand (TRAIL) to TRAIL receptors on neutrophils accelerates neutrophil apoptosis.³⁹ One of four known TRAIL receptors is unable to transduce the death signal and functions as a decoy receptor; this receptor is reduced in SLE patients with neutropenia and is upregulated by steroid therapy.

Lymphopenia occurs with a reported incidence of 19–62% (Table 51.4). There are reduced numbers of circulating CD4 T cells in SLE and a decreased CD4-to-CD8 ratio. Lymphocytotoxic antibodies, increased apoptosis related to Fas and Fas ligand upregulation, and increased serum IL-10 levels have all been implicated in pathogenesis. It has been suggested that B cells expressing the 9G4 idiotype found on V_H 4.34 heavy chains may be responsible for production of anti-lymphocyte antibodies. In general, in the absence of recurrent infection, leukopenia in SLE rarely warrants treatment. Increased steroids may increase the leukocyte count but also contribute to the risk of infection.

Thrombocytopenia

Low platelet counts are seen in approximately 25% of patients, although severe thrombocytopenia is reported in fewer than 10% of patients (Table 51.4). Immune-mediated consumption is the most frequent cause, but rarely platelet consumption occurs together with a microangiopathic hemolytic anemia, TTP or as part of the hemophagocytic syndrome. A pathogenic role for antibodies against platelet membrane glycoproteins (IIb/IIIa antigen) is well established.⁴⁰ Other possible mechanisms include antibodies to thrombopoietin, and antiphospholipid and anti-CD40-ligand antibodies that bind to platelets, resulting in platelet sequestration.

CENTRAL AND PERIPHERAL NERVOUS SYSTEM

Neurologic and psychiatric manifestations of SLE are diverse and frequently occur irrespective of systemic disease activity. Neuropsychiatric symptoms may be focal or diffuse, peripheral or central; they may occur in an isolated or complex fashion. Little is known about the pathogenesis of most of these syndromes.

In 1999 the ACR developed a nomenclature and case definitions for neuropsychiatric lupus (NPSLE).⁴¹ The consensus committee developed reporting standards, case definitions, and recommendations for laboratory and imaging studies for 19 neurologic, psychiatric, and cognitive syndromes (Table 51.5). Diagnosis of an NPSLE syndrome requires the exclusion of infections, metabolic disturbances, bleeding disorders, malignancy, and medication toxicities. Using this new nomenclature, NPSLE is common, with a prevalence of 57–95%. Headache is the most frequent manifestation, followed by mood disorders, strokes, and transient ischemic attacks, cognitive dysfunction, seizures, and psychosis. Polyneuropathy, demyelinating disease, mononeuritis, myasthenia gravis, chorea, cranial neuropathy, myelopathy, and Guillain-Barré syndrome are uncommon.

Focal presentations attributable to specific central nervous system lesions occur frequently in association with anti-phospholipid antibodies. These presentations include strokes, transient ischemic attacks, seizures, movement disorders, and cranial neuropathies. Global dysfunction without focal impairment presents as intractable headaches, coma, delirium, cognitive dysfunction, and psychiatric syndromes, e.g., psychosis, mania, and depression. Cerebrospinal fluid (CSF) examination is useful for excluding infection or malignant cells. Active NPSLE is characterized by a lymphocytosis and evidence of intrathecal immunoglobulin synthesis with elevated total protein, IgG index, and oligoclonal bands; however, these abnormalities are not consistently present. While numerous autoantibodies (ANA, anti-dsDNA, anticardiolipin, anti-ribosomal P, anti-neuronal) and various cytokines have been identified in the CSF of patients with SLE, none is specific for active NPSLE and routine testing is not recommended. MRI is extremely sensitive for detection of structural lesions and new ischemic lesions; it is not helpful in differentiating between active NPSLE and old changes. Furthermore MRI studies may be normal in patients with psychiatric syndromes and global dysfunction.⁴² Positron emission tomography (PET) and single-photon emission computed tomography (SPECT) scans measuring cerebral glucose uptake and blood flow, respectively, correlate to a limited extent with diffuse NPSLE. These scans must be interpreted carefully since atrophy with neuronal cell loss leads to changes in metabolism and blood flow. Atrophy is a common finding on brain imaging in SLE and newer imaging techniques demonstrate that neuronal function may be compromised during flares of NPSLE. The sensitivity and specificity of the newer imaging modalities, magnetic resonance spectroscopy, and functional MRI for detecting active NPSLE are currently under investigation. Cerebral angiograms may be helpful if a diagnosis of cerebral vasculitis is considered; however, central nervous system vasculitis is rare. Autopsy studies have documented the presence of true vasculitis in only 5–8% of cases. More commonly, a bland vasculopathy with degenerative and proliferative changes in small vessels, perivascular infiltrates, microinfarcts, and microhemorrhages is present.

There are no serologic tests specific for NPSLE. Serologic evidence of disease activity (elevated anti-DNA antibodies and low complement) may help to diagnose NPSLE, particularly if combined with other clinical signs of active disease. However, NPSLE may also flare in the absence of serologic and clinical disease activity. Anti-neuronal and anti-ribosomal

 - >> Induction of remission
 - >> Maintenance of remission
 - >> Preservation of organ function
- >> Suppression of immune activation
 - >> Modulation of the immune response
- >> Management/prevention of drug-related toxicities

P antibodies are known to bind neurons; however, no functional consequences of these antibodies binding to tissue have been elucidated and no clear associations with NPSLE have been identified.⁴³ Antibodies to neuronal NMDA receptors (NMDAR's) have been identified in the sera, CSF, and brain of SLE patients and are associated with cognitive and depressive syndromes in some SLE patients. Animal studies demonstrate that binding of these autoantibodies to the NMDAR results in excitotoxic death of neurons leading to cognitive and emotional disturbances.⁴⁴ In summary, the clinical evaluation of a patient with presumed NPSLE involves an exhaustive search for other potential causes, and is guided by the presence of focal or diffuse symptomatology.

Antiphospholipid antibody syndrome is described in detail in Chapter 61.

Drug-induced lupus

Until recently, drug-induced lupus referred to a clinical syndrome that resembled mild lupus and occurred following exposure to a number of drugs (most notably procainamide, hydralazine, chlorpromazine, and methyldopa). Constitutional symptoms, musculoskeletal symptoms (arthritis and arthralgia), and serositis were common and renal and

neurologic involvement were rare. Autoantibodies, including a positive ANA and anti-histone antibodies, were characteristically observed while anti-DNA and anti-Sm antibodies were unusual. Symptoms generally began weeks to months following the initiation of the inciting therapeutic agent and resolved within weeks after the drug was discontinued; autoantibodies could persist for up to 12 months. Host factors such as a decreased ability to metabolize the drug (e.g., slow acetylation of procainamide and hydralazine) contributed to the risk of developing drug-induced lupus. Multiple potential mechanisms resulting in the loss of self-tolerance have been suggested for this classic model. One of the most extensively explored is inhibition of DNA methylation, resulting in overexpression of co-stimulatory molecules such as LFA-1 on T cells and enhanced T-cell help.⁴⁵

Since the introduction of anti-TNF agents, a different type of drug-induced lupus has been recognized. Up to 30% of patients receiving TNF blockade develop autoantibodies, including a positive ANA and antibodies to dsDNA. A minority develop a drug-induced clinical syndrome that can include anti-DNA antibodies, nephritis, and vasculitis. The pathogenesis of immunologic dysregulation resulting in the formation of autoantibodies and triggering of clinical disease is not known, although it is similar to observations made in the NZB/W mouse model of lupus.⁴⁶

Treatment

The goals of lupus treatment are to stop and reverse ongoing organ inflammation, prevent or limit irreversible organ damage, and to suppress the immune response driving the inflammation. The efficacy of therapeutic agents must be balanced against their potential toxicity. Thus, treatment must be tailored to the individual patient and individual disease manifestations. In general, milder disease requires treatment with less potent or lower doses of anti-inflammatory and immunosuppressive medications than more active, severe disease affecting major organs such as the kidney or brain (Table 51.6). However, individual patient responses to a given medication will vary and patients must be monitored closely for a clinical response as well as toxicity.

Some genetic factors predicting risk of toxicity or therapeutic benefit for individual agents have been identified. Polymorphisms of a key enzyme in the metabolism of azathioprine, thiopurine methyltransferase (TPMT), are common; 0.3% and 11% of Caucasians are homozygous and heterozygous (respectively) for mutations associated with a lack of expression of TPMT.⁴⁷ TPMT-deficient patients are especially susceptible to leukopenia and pancytopenia associated with azathioprine. Cyclophosphamide is metabolized to its active form by cytochrome P450. Individuals heterozygous or homozygous for a specific cytochrome P450 polymorphism (CYP2C19*2) have a lower probability of developing premature ovarian failure, but also show a poorer response to therapy.⁴⁸

Although corticosteroids are the foundation of treatment, exposure must be minimized to the greatest extent given their multiple and frequent side effects, including hypertension, diabetes mellitus, increased susceptibility to infection, bone loss, and weight gain. Currently available agents that are commonly used include antimalarials such as hydroxychloroquine (400 mg/day), anti-metabolites such as azathioprine (1–2.5 mg/kg per day), methotrexate (7.5–25 mg/week), leflunomide (10–20 mg/day), and mycophenolate mofetil (2–3 g/day) and alkylating agents such as cyclophosphamide (monthly pulse 0.5–1.0 g/m²). When more conventional therapies have failed, anecdotal reports, case series, and open-label studies suggest that use of intravenous immunoglobulin (2 g/kg over 2–5 days), thalidomide (50–100 mg/day) or cyclosporine (3–5 mg/kg per day) may be beneficial. Medications such as dapsone, danazol, and chlorambucil may be efficacious in cutaneous disease, hematologic disease, and in severe refractory disease (respectively), but in general these medications are not commonly used due to their toxicity, and the introduction and availability of better-tolerated, efficacious agents.

There are a number of newer agents on the horizon for treatment of SLE. Some are currently available but approved for other indications, whereas others are still in developmental stages. These therapies, in general, have more specific immunologic targets than standard treatments. Although there are multiple agents that have been tested in animal models of disease, we will only focus on therapies that have been given to humans.⁴⁹ Some

Table 51.6 Treatments for systemic lupus erythematosus disease manifestations

	NSAIDs	Antimalarials †	Low-dose corticosteroids (< 0.5 mg/kg per day)	High-dose corticosteroids (> 0.5 mg/kg per day) ‡	Azathioprine	MMF	CTX

†Antimalarials should be given to all patients to sustain remission and reduce damage
 ‡High-dose corticosteroids are required for remission induction or an inadequate response to low dose therapy
 CTX, cyclophosphamide; MMF, mycophenolate mofetil; NSAIDs, nonsteroidal anti-inflammatory drugs.

agents are antigen-targeted. DNase I cleaves DNA, a target, and perhaps inciter, of the lupus autoimmune response. Abetimus sodium (LJP 394), a tetramer of short double-stranded oligonucleotides binds anti-DNA antibodies and may tolerize DNA-specific B cells. Results of phase II and III studies show that treatment with abetimus sodium results in a decrease in antibodies to dsDNA but clinical efficacy remains unproven. Edratide (TV4710) is a peptide derived from the CDR1 on an anti-DNA antibody. Vaccination with this peptide is currently in clinical trial.

B-cell-directed therapies (and their corresponding targets) include epratuzumab (anti-CD22 antibody) targeting all B cells, rituximab (anti-CD20 antibody) targeting all B cells except plasma cells, belimumab (anti-BAFF antibody) targeting a B-cell growth factor, TACI-Ig which blocks both BAFF and APRIL, and antibody to the receptor for IL-6, another B-cell survival factor. R406, an inhibitor of syk, which is a crucial kinase that is activated after BCR engagement, is designed to block B-cell activation.

Potential therapies aimed at the dendritic cells include vitamin D, which blocks dendritic cell maturation and T-cell activation, abatacept (CTLA4-Ig), now approved for use in rheumatoid arthritis, which blocks the interaction of T cells with B7 molecules on dendritic cells and so blocks T-cell activation, and inhibitory oligodeoxynucleotides, which block TLR9 signaling and dendritic cell maturation. Hydroxychloroquine, a standard agent for lupus, interferes with toll-like receptor (TLR)7 and TLR9 signaling by preventing acidification of the endosomal compartment.

Other potential therapies are directed against IFN- α or IL-12, a dendritic cell cytokine (both a monoclonal antibody and an inhibitor). The monoclonal antibody against IL-12 has demonstrated efficacy in Crohn's disease. Studies of a monoclonal antibody against IFN- α are under way. Novel interventions directed at T cells include therapies interfering with the CD40-CD40L interaction. Initial clinical studies of antibodies against T-cell CD40L were accompanied by an unacceptable increase in thrombosis. Thus, antagonistic antibodies to CD40 are under development.

Eclizumab is an antibody directed against C5 which blocks cleavage of C5 and the subsequent triggering of the complement cascade. C5b is a potent chemotactic factor for both neutrophils and monocytes. Alicaforsen, an antisense oligodeoxynucleotide that inhibits ICAM-1 expression, decreases inflammation in both rheumatoid arthritis and Crohn's disease. Efalizumab, a monoclonal antibody against CD11a (a LFA-1 subunit that interacts with ICAM-1), benefits patients with psoriasis. Although there are no chemokine targeted therapies in clinical trial in lupus, a CCR1 antagonist slowed disease progression in a mouse model of lupus and has been tested in patients with rheumatoid arthritis. FTY720, an agonist for the sphingosine-1 phosphate receptor which prevents egress of lymphocytes from secondary lymphoid organs and inflamed tissues, has beneficial effects in the MRL/lpr mouse model of lupus; it has been given to transplant recipients and to patients with multiple sclerosis. TNF- α is a potent inflammatory cytokine; TNF- α antagonism results in disease reduction in rheumatoid arthritis. However, up to 20% of patients develop autoantibodies and a minority develop lupus. TNF- α is involved in renal inflammation in SLE and monoclonal antibody to TNF- α appears to improve lupus nephritis, showing that agents can abort inflammation and yet exacerbate autoimmunity. The potential efficiency and safety of short-term use of TNF- α blockade in lupus are under study. Another potential therapy in patients with severe unremitting lupus is ablation with high-dose chemotherapy followed by immune reconstitution using

autologous or allogeneic hematopoietic stem cells. Initial efficacy, the associated toxicity and morbidity of these treatments, as well as the durability of both response will be determined in a clinical trial which is now under way.

CONCLUSIONS

SLE is a heterogeneous disease, with different patterns of immune dysregulation leading to ANA production and target organ inflammation. The goal in therapy must be to eliminate autoreactivity while maintaining immunocompetence. Restoration of normal immune homeostasis and immunocompetence requires treatment during and after remission induction with multiple agents, each modulating a different aspect of immune dysregulation. Among the challenges we now face are the careful phenotyping of patients to identify etiopathologically distinct subpopulations and new clinical trial designs to allow the use of combinations of agents, each of which alone may have a negligible effect on disease course.

Rheumatoid arthritis

Andrew P. Cope

52

Rheumatoid arthritis (RA) is one of the most common chronic inflammatory diseases and has become the prototype disease entity for defining the molecular and pathological basis of chronic inflammatory syndromes. The term 'rheumatoid arthritis' was coined by Garrod in 1859. However, this was probably an inappropriate use of the term because it encompassed polyarticular osteoarthritis, as well as inflammatory polyarthritis. For many years there has been considerable debate as to whether RA is in fact a new disease, a hypothesis based more on negative data and inconclusive deductions from archive material, including the visual arts and archaeological artifacts. In spite of references to inflammatory affections of joints by the likes of Galen, Sydenham and Heberden, the first convincing case reports of the disease, described in terms that would be recognizable today, were published in 1800 by Landré-Beauvais, who labelled the disease 'la goutte asthénique primitive'.¹ This description was distinct, as all patients were female, an observation that was significant when the most important differential diagnosis at that time was polyarticular gout, a disease predominantly of males.

Today we recognize RA as a chronic inflammatory disorder of joints of unknown etiology in which the major target tissue is the synovial lining of joints, bursae and tendon sheaths.² Despite being traditionally considered an autoimmune disease, RA differs from organ-specific autoimmune disease entities in several respects. From the outset of RA, the immunoinflammatory process, driven by cytokines and other inflammatory mediators, promotes the activation and proliferation of stromal joint tissues, in particular the fibroblastic synovial lining layer. In contrast, organ-specific autoimmune diseases such as type I diabetes or autoimmune thyroiditis are characterized by an antigen-driven inflammatory process that leads directly to cellular destruction of pancreatic β -islet or thyroid tissue cells. It is only during the later phase of chronic, severe and progressive disease (representing only a subset of patients) that the invasive synovium, or pannus, invades and erodes underlying cartilage and bone. Unlike some autoimmune diseases that target single organs or tissues, RA is a systemic inflammatory disease that probably encompasses a heterogeneous syndrome. It exhibits marked variations in clinical expression that most clinicians today would acknowledge is more than one disease entity. Indeed, over a period of several decades it has become increasingly apparent that the disease is heterogeneous, not

only clinically, but also pathologically, serologically and genetically, presenting major challenges to the immunologist and physician.

■ EPIDEMIOLOGY ■

The incidence of RA (the rate of new cases arising in a given period) is 0.1–0.2 per 1000 of the population for males, and 0.2–0.4 per 1000 for females.³ These rates plateau between the ages of 45 and 75 years in some series but can increase steadily with age until the seventh decade, declining thereafter. The largest difference in incidence between the sexes occurs in those under 50 years of age. Recent evidence indicates that the incidence may be in decline, suggesting an environmental influence. The disease prevalence (the number of existing cases) should ideally include all past and inactive cases. For RA, large cross-sectional population samples indicate that the figure ranges from 0.5% to 2% for caucasian European and North American populations over the age of 15, with a female to male excess of 2 to 4.³ Despite similar prevalence estimates for these geographically diverse populations, greater diversity has been documented for rural African populations, where the prevalence has been reported to be as low as 0.1%, and Native Americans (including the Pima, Yakima and Chippewa tribes), where the prevalence may be as high as 5%.

Complex polygenic autoimmune syndromes such as RA are diseases of low penetrance, where thresholds of disease expression may be higher in males. This is based in part on the observation that the increased risk of disease in siblings of probands is rather small. Twin studies provide perhaps the most compelling evidence for genetic effects, given the excess concordance rates for monozygotic (12–15%) compared to dizygotic twins (<5%, and probably nearer to 3.5%).⁴ Compared to a background prevalence of 1% in outbred populations, these figures translate to a striking contribution of genetic factors, calculated to be of the order of 53–65%.⁵ This leaves a substantial contribution for disease susceptibility from environmental factors, influenced by occupation, socioeconomic status, exposure to infectious pathogens and lifestyle factors.

Two of the more intriguing factors contributing to disease occurrence are age and gender. Age-associated changes in susceptibility to infection, neoplastic disease and autoimmunity suggest that a common mechanism

KEY CONCEPTS

IMPORTANT RISK FACTORS FOR DEVELOPING RA

- >> Female gender
- >> Nulliparity, or during first three months postpartum
- >> Low androgen or high estrogen status (in men)
- >> Smoking >25 cigarettes per day for >20 years. Relative risk increased to 15-fold depending on HLA-DRB1 status
- >> Prolonged exposure to unidentified environmental antigens (e.g. infectious pathogens)
- >> Urban dwelling
- >> Immune senescence
- >> Serum autoantibodies to citrullinated protein antigens (anti-CPA)
- >> First-degree relative with RA. Relative risk 1.5
- >> Inheritance of allelic variants including *HLA-DRB1* and *PTPN22*

could be responsible. Immune senescence is one possibility, where age-related decline in host immunity is characterized at the cellular and molecular level by massive expansions of lymphocyte clones, corresponding contractions of the naïve T- and B-cell repertoires, and telomere erosion of leukocytes, indicative of an extensive proliferative history.⁶ When combined with oxidative stress and a range of biochemical derangements of pathways integral to antigen responsiveness and immune regulation, these factors may combine to (1) increase susceptibility to foreign pathogens; (2) augment reactivity to self-tissue antigens (themselves modified post-translationally as a consequence of the ageing process); and (3) generate a repertoire of lymphocytes defective in terms of tumor surveillance. Thus, immune senescence should be considered a risk factor for RA.

The female preponderance implies that hormonal and reproductive factors strongly influence risk. On the one hand, nulliparity is a risk factor for RA. Women entering the first 3 months of the postpartum period are also at increased risk. By contrast, oral contraceptive use, pregnancy and breastfeeding are associated with reduced risk or less severe disease.⁷ Several possible immune mechanisms have been proposed. For example, maternofetal mismatch at the MHC locus has been associated with higher disease remission rates during pregnancy. In mice, pregnancy has been shown to be associated with quantitative changes in the numbers of regulatory T cells. An influence of hormonal factors is further suggested in studies of men where disease is associated with lower androgenic testosterone and dehydroepiandrosterone (DHEA) levels and increased estradiol, compared to a cohort of healthy control male subjects.

ETIOLOGY AND PATHOGENESIS

ENVIRONMENTAL AND NONGENETIC FACTORS

Most studies have reported an association between RA and smoking. One of the largest studies comprising over 370 000 women from the Women's Health Cohort Study reported a relative risk of 1.4 for women

who smoked more than 25 cigarettes per day for more than 20 years, compared to nonsmokers.⁸ The association appears to be more closely related to duration of smoking rather than the amount of tobacco exposure, and may influence severity, as smokers are more likely to have seropositive, erosive disease with extra-articular manifestations. The effect may be fully reversible in those individuals who stop smoking for 10 years or more. Further evidence of gene-environment interactions with respect to smoking have been documented more recently in a population based case-control study of Swedish RA patients.⁹ In this study the relative risk of developing rheumatoid factor-positive (RF⁺) RA was calculated according to smoking status and HLA-DRB1 genotype. The relative risk of developing RA increased from 2.5 in nonsmokers with disease-associated HLA-DRB1 genes to 7.5 and 15.7 in smokers who carried one or two copies of the susceptibility alleles, respectively. The association between smoking and seropositive disease was explored further in a follow-up study that demonstrated more robust associations with smoking, HLA-DRB1 status, and the presence of autoantibodies to citrullinated protein antigens (anti-CPA).

Being female, a smoker, and carrying specific disease-associated genes may be highly associated (but not sufficient) for the initiation of chronic inflammatory arthritis. Other environmental triggers may be involved. Not least among these are exposure to foreign pathogens.¹⁰ This association has gained much credibility because of the presumed link not only between infection and autoimmunity but also between immunodeficiency and autoimmune disease. Nonetheless, no single pathogen or group of pathogens has been defined. This could imply that aberrant host responses (either exaggerated innate inflammatory responses or failure to terminate such responses) may occur following a wide range of infectious insults. Indeed, bacteria such as *Proteus mirabilis*, or bacterial products including superantigens, *Mycoplasma* species, viruses (including herpes family, parvovirus and retroviruses) and fungi have all been implicated, but data have been insufficient to prove causation. Epstein-Barr virus (EBV) infection has been a particularly attractive candidate as infection is common, antibodies to EBV nuclear antigens have been reported in patients with RA, EBV is a polyclonal activator of B lymphocytes, EBV-specific T cells reactive to EBV gp110 have been identified in RA synovial joints, and EBV RNA has been isolated from the synovium.

Another possible link between infection and autoimmunity comes from the observation that components of the mycobacterium used in Freund's adjuvant to induce arthritis in rodents include heat shock proteins (hsp), especially hsp65, which in turn promotes T cell-specific immunity.¹¹ One hypothesis suggests that these highly conserved chaperones may cross-react with self proteins, thereby provoking reactivity to host tissues. More recent data suggest that exposure of the immune system to hsp at sites of tissue damage evokes a danger signal that may ultimately result in the expansion of subsets of regulatory T cells that contribute to the resolution of the inflammatory response.¹¹

IMMUNOGENETICS

RA is a clinically heterogeneous disease and so it has been very difficult to identify disease susceptibility genes, in spite of heritability estimates of up to 60%. With the exception of the MHC, these genes confer low to moderate risk and have low penetrance. Nevertheless, five genome-wide linkage scans of multiplex families with RA have established an important contribution of the MHC.¹² This lends support to a wealth of epidemiological and genetic data describing associations between RA and specific

HLA-DRB1 alleles, in particular HLA-DR4 subtypes. While this association was first described by Stastny in the 1970s, it was shown more than a decade later that susceptibility to RA across different ethnic populations correlated closely with the expression of a specific consensus amino acid sequence (referred to as the 'shared epitope,' hereafter SE) within the HLA-DR β chain α helix (Table 52.1).¹³ This sequence was subsequently shown by several groups of investigators to be encoded by HLA-DRB1 alleles, including HLA-DR4 (*0401, *0404, *0405 and *0408), but also HLA-DR1 (*0101), DR6 (*1402) and DR10 (*1001) alleles, among others. These shared epitope-carrying alleles have recently been reclassified (Table 52.1). According to this model, RA is associated with the rheumatoid arthritis-associated (RAA) shared epitope sequence (72–74 positions) and the association is modulated by the amino acids at positions 70 and 71, resulting in six genotypes with RA risks varying from 4.4 to 22.2. On the other hand, the finding of DERA encoding HLA-DRB1 alleles (DRB1*0103, *0402, *1102, *1103, *1302 and *1304) conferring lower disease risk, and more importantly reduced radiographic progression in RA even in the presence of one copy of the SE, raises the possibility that specific subsets of MHC class II genes may confer an independent protective role.¹⁴

Specific genotypes co-segregate with distinct clinical features.¹⁵ For example, in population-based studies different HLA-DRB1 alleles influence the severity of disease, with DRB1*0401 being found in patients with severe, seropositive, erosive RA (often with extra-articular features such as vasculitis and Felty's syndrome in *0401 homozygous or *0401/*0404 compound homozygote individuals), whereas DRB1*0101 and *1001 are observed at a higher frequency in patients with less severe, seronegative, nonerosive disease. Inheriting two copies of alleles that express the consensus sequence increases disease penetrance, time of onset and severity. Thus, rather than a hierarchy of phenotypes of a single disease, these genetic associations, which are by no means uniform, are reflected clinically as distinct disease entities.

On the basis of early observations, two principal models were proposed to account for the association between RA and the consensus DR β chain sequence.¹⁶ Both were based on the assumption that the shared epitope is the critical genetic element linked directly to disease. The first model proposed that the shared epitope determines specific peptide binding, and that 'pathogenic' peptides bind only to disease-associated HLA class II molecules (Fig. 52.1). This model predicted that a gradient of affinities of disease-inducing peptide for MHC class II molecules might account for the differences in susceptibility and/or severity conferred by different HLA-DR molecules. Along the same lines, disease-associated alleles may preclude the binding of peptides required for the generation of naturally occurring regulatory T cells specific for self-peptide antigens. The second model proposed that the shared epitope influences T-cell receptor (TCR) recognition by binding and selecting autoreactive T cells during thymic maturation, and expanding these populations in the peripheral compartment; again, perturbations of a repertoire of regulatory T cells could arise through opposing influences of the shared epitope sequence.

Two recent lines of experimental evidence provide further insights into HLA-disease associations. The first is the association between HLA-DR4 subtypes and telomere erosion in RA patients and healthy donors, detectable before the age of 20.⁶ Telomeres are reiterative nucleotide sequences found at the end of chromosomes that become eroded with successive rounds of cell division. Their loss has been associated with aging and immunosenescence. Whether this implies a direct contribution

of HLA-DR4 expression to accelerated differentiation of hematopoietic cells in the context of a chronic inflammatory process is intriguing, but certainly warrants further investigation. The second line of evidence pointing to specific functions of SE⁺ alleles has arisen through analysis of autoantibodies in RA patients typed at the HLA-DRB1 locus.¹⁷ These studies, replicated in European and US RA cohorts, demonstrated associations between SE frequencies and antibodies to cyclic citrullinated peptides (anti-CCP). Specifically, compared to healthy controls, the odds ratio for the association between one or two copies of the SE and anti-CCP positivity was 4.4 and 11.8, respectively. These findings point to SE associating not with RA per se, but with a clinical phenotype, in this case autoantibodies to modified proteins.¹⁷

Linkage studies have generated only nominal evidence of linkage at non-MHC loci. Nevertheless, leading candidates include genomic fragments on chromosomes 1p13, 1q41-43, 6q16, 16p and 18q.¹² This has meant that large cohorts are required to confirm evidence of definite linkage across these intervals. Nonetheless, one allelic variant whose association with RA has now been validated in multiple disease cohorts is found in the gene *PTPN22*, which encodes the hematopoietic protein tyrosine phosphatase Lyp. Combining all studies, the odds ratio is no higher than 1.8. Some studies have revealed an association between the RA-associated variant *PTPN22* (R620W) with RF and anti-CCP positivity, which is also independent of SE. The data suggest that *PTPN22* may influence autoantibody production and be involved in the initiation of disease, as distinct from regulating severity. *PTPN22* mutations have also been described in type I diabetes, a subset of systemic lupus erythematosus patients, oligoarticular JIA, vitiligo, Addison's disease and autoimmune thyroid disease, but not multiple sclerosis or psoriasis, pointing to a more generic link with pathogenic autoantibodies in a range of syndromes.¹² Recently, the disease-associated Lyp 620W variant was shown to be a gain-of-function mutant, leading to hyporesponsiveness to TCR engagement through attenuated receptor proximal signaling, reduced IL-2 production and proliferative responses. Although the genetic data suggest that the impact of this mutation may be weak relative to MHC genes, this hyporesponsive phenotype could alter thymic selection, or mechanisms of peripheral tolerance that are critically dependent on TCR signaling.

SYNOVIAL PATHOLOGY

RA targets diarthrodial joints, structures characterized by hyaline cartilage lining opposing articulating surfaces and a cavity of viscous synovial fluid lined by synovial membrane lacking a basement membrane but encased by a fibrous joint capsule. Normal synovial tissue comprises a lining layer, no more than a few cells in depth, of stromal fibroblast-like synoviocytes (FLS; also known as type B synoviocytes) and sublining macrophages (type A synoviocytes). The synovium serves to line noncartilaginous surfaces, and although blood vessels are sparse, it functions to provide essential nutrients to avascular structures, including cartilage, tendons and bursae.

INCREASED VASCULARITY AND CELL MIGRATION

The range of pathology observed in patients with RA perhaps most convincingly emphasizes the heterogeneity of the disease. The earliest changes observed relate to increases in vascularity characterized by vascular congestion and thrombosis with obliteration of small vessels in

Table 52.1 Classification of HLA-DRB1 alleles according to the third hypervariable region of the DR β chain and their association with RA in French caucasian patients (Data adapted from du Montcel et al. New classification of HLA-DRB1 alleles supports the shared epitope hypothesis of rheumatoid arthritis susceptibility. Arthritis Rheum 2005; 52: 1063–1068)

Fig. 5.21 Crystal structure of a collagen II peptide/HLA-DR4 complex ribbon model of an immunodominant collagen II peptide (1168–1180) complexed to HLA-DR4 (DRA*0101/DRB1*0401); a view of the MHC/peptide complex as seen from the T-cell surface. DR α - and DR β -chain helices are shown in red, whereas the β -pleated sheet comprising the floor of the peptide-binding groove is shown in blue. Residues 67–74 of the DR β chain, components of the third hypervariable region, derive the ‘shared epitope.’ The ball-and-stick model of the CII peptide is shown. Interacting residues of the peptide position 4 (Asp – orange) and DR β -chain residue (β 71Lys – green), which make up part of pocket 4, are depicted as van der Waals’ spheres. Differences in amino acid sequence between the closely related disease associated DRB1*0401 and nonassociated DRB1*0402 gene products are illustrated. Note that whereas Arg would not be favored at position 4 in the peptide, modification of Arg→Cit by deimination would be permissive. (Figure generated by R. Visse and A. Cope, based on crystal data derived by Wiley and colleagues in Dessen A, Lawrence CM, Cupo S, et al. X-ray crystal structure of HLA-DR4 (DRA*0101, DRB1*0401) complexed with a peptide from human collagen II. *Immunity* 1997; 7: 473–481.)

association with perivascular inflammatory infiltrates.¹⁸ Hyperplasia of the synovial lining layer is a typical early finding. These changes are rather nonspecific and certainly not diagnostic.

A key checkpoint that defines the switch from acute to chronic persistent inflammation is the sustained activation of microvascular endothelium, phenotypic changes in the high endothelial venules (reminiscent of tissue injury), and the concomitant upregulation of adhesion molecules such as intercellular adhesion molecule (ICAM)-1 and vascular cell adhesion molecule (VCAM)-1.¹⁹ With chemoattractants derived from synovial stromal cells, these changes herald the rolling, adhesion and transmigration of mononuclear cells through endothelial barriers into the synovial membrane, and contribute to the progressive synovial hypertrophy and hyperplasia, sometimes with villous-like projections more typical of chronic, established inflammation. Neovascularization further promotes the influx of inflammatory cells. To what extent this is driven by the hypoxic environment is not clear, but angiogenic growth factors such as vascular endothelial growth factor (VEGF) and hypoxia-inducible factor (HIF) make important contributions.²⁰ It has been proposed that influx of inflammatory lymphocytes and cells of monocytic lineage far outweighs the egress of cells from synovial tissue, possibly due to chemokine gradients. Once in the synovium egress may be regulated or blocked

through integrin/adhesion molecule interactions, e.g., between antigen-specific T cells and dendritic cells/APC, through TCR-dependent signals that abrogate chemokine responsiveness, or perhaps through highly selective and specific inactivation of chemokines by proteolysis, e.g., stromal-derived factor (SDF)-1 cleavage by cell surface dipeptidyl peptidase CD26. Recent data suggest that generalized cytokine and inflammatory signals rather than antigen drive may trigger the migration of effector memory T-cell subsets such as CD4⁺CD28^{null}CXCR4⁺NKG2D⁺ T cells from lymph nodes to synovium.²¹ This is an important distinction because it suggests that nonspecific innate inflammatory signals rather than antigen-specific signals might precipitate disease flares in patients with RA.

ORGANIZATION OF LYMPHOID TERTIARY MICROSTRUCTURES

Tissue microstructure dictates and facilitates immune responses in secondary lymphoid organs but also in the gastrointestinal tract. The same concept probably holds for peripheral tissues in chronic inflammatory disease, where the topology of infiltrates appears to be a stable trait over time. Thus, in established disease the rheumatoid synovium

Fig. 52.2 Lymphoid follicular structures in inflamed RA synovial tissue. A characteristic hematoxylin and eosin-stained tissue section from a patient with active RA showing a large follicular-like structure. This section is also stained with monoclonal antibodies to CD3 ϵ , followed by a three-step immunoperoxidase staining protocol (CD3 $^{+}$ T cells stained dark red). (Image provided by and reproduced with kind permission of Professor P.P. Tak.)

appears to be uniquely suited to supporting distinct patterns of cellular infiltrates.²² These include diffuse, rather disorganized lymphocytic infiltrates, and comprise the most common form of synovitis. In 40–50% of patients more organized follicular structures may exist (Fig. 52.2). Based on immunohistochemical analysis, approximately 25% of these follicular structures include organized germinal centers in which there are zones of proliferating B cells undergoing affinity maturation, in addition to a distinct T-cell zone. In aggregates lacking germinal centers, follicular dendritic cells are also absent. A fourth histological pattern has been described in a much smaller subset of patients characterized by granulomatous reactions. From a clinical standpoint, it has been suggested that these distinct patterns not only reflect the heterogeneity of the disease, but also a spectrum of disease severity, with the presence of germinal centers or granulomatous reactions in tissues that are densely vascularized being associated with more severe, destructive disease. Several molecular determinants of synovial lymphoid structures have been defined. For example, the presence of germinal centers has been associated with tissue production of selected chemokines and the cytokine lymphotoxin.²²

There is growing evidence from murine models that mononuclear cells invading the synovium can also originate from the bone marrow, passing through enlarged bone canals that connect the marrow to the synovium. This may explain the orientation and localization of invading tissue or ‘pannus’ (derived from the Greek, meaning ‘tongue’). The regulation of this process is not known, but may be a key checkpoint for the initiation and tissue tropism of the inflammatory process. It also has a clinical correlate in early RA in terms of periarticular osteopenia on plain radiographs and bone marrow edema seen by magnetic resonance imaging (MRI).

GENE EXPRESSION SIGNATURES

Gene array technology has now permitted analysis of synovial tissue at the whole genome level, and, like genetic, serological and histological analysis, provides further evidence of disease heterogeneity. This strategy makes the assumption that each disease phenotype should be represented in gene expression signatures of multiple genes. Remarkable variation in gene expression signatures has been observed, although initial analyses seem to suggest that these signatures can be divided broadly into two groups.²³ The first is characterized by upregulation of immune response and inflammatory genes; these tissues are enriched for MHC and immunoglobulin gene products. In some tissues this signature may resemble an antiviral response consistent with prior infectious insult, and, more specifically, a STAT-1-dependent gene signature (promoting protective or proinflammatory effects).²³ This has also been observed in peripheral blood lymphocytes (PBL) from patients. The second group is more indicative of tissue remodeling, more reminiscent of that seen in osteoarthritis. Most interestingly, distinct FLS genotypes and phenotypes match the type of RA tissue from which they derived. For example, FLS signatures from high-intensity inflammatory tissue resemble that of TGF- β /activin A-induced expression profiles in myofibroblasts, whereas growth factors such as insulin-like growth factor 2 and insulin-like growth factor-binding protein 5 characterize FLS from tissues with low-intensity inflammation. These data support the notion of RA heterogeneity being reflected in FLS as a stable, if not a transformed, trait. They would also be consistent with a model of T cell-dependent RA that progresses with time to a relatively T cell-independent process, characterized by autonomous, invasive and aggressive FLS.²⁴

IMMUNOBIOLOGY OF RA

INITIATION OF THE IMMUNE RESPONSE

Synovial fibroblasts are exquisitely sensitive to inflammatory cytokines such as IL-1, TNF- α and IL-6.²⁴ Accumulating evidence indicates that fibroblast-like synoviocytes (FLS) also express a range of Toll-like receptors (TLRs) that may respond to exogenous, pathogen-derived PAMPs, or indeed a growing range of self-tissue proteins.²⁵ Endogenous ligands especially relevant to inflammatory arthritis include heat shock proteins, fibrinogen fragments, antibody–DNA complexes, high-mobility group box (HMGB)-1 and hyaluronan oligosaccharides. Indeed, adjuvant arthritis models, as well as the streptococcal cell wall model, are dependent on such ligand receptor pathways. Recent data suggest that synovial FLS, as well as synovial macrophages, express TLR2 *in situ*. Expression is upregulated following stimulation with IL-1 and the TLR2 ligand peptidoglycan. TLR2 engagement induces cytokines such as IL-6, matrix metalloproteinases, adhesion molecules, and an array of chemokines, including granulocyte chemotactic protein (GCP)-2, RANTES, monocyte chemoattractant protein (MCP)-2, IL-8, growth-related oncogene-2, and to a lesser extent, macrophage-inflammatory protein 1 α , MCP-1, EXODUS, and CXCL-16. Data suggest that TLR3, TLR4, TLR7 and TLR9 are also expressed at mRNA and possibly protein level,²⁵ and may augment inflammatory cytokine expression by dendritic cells from patients with RA.

Dendritic cells are likely to be important antigen-presenting cells in RA. Indeed, the proinflammatory environment would certainly favor maturation of DC in regional lymph nodes as well as in inflamed

tissue.²⁶ Thus, in peripheral blood, dendritic cell precursors express either an immature CD33^{dim}CD14^{dim}CD16⁻ or a more mature HLA-DR/DQ^{bright}CD11c⁺CD33^{bright}CD14^{dim} surface phenotype typical of myeloid DC (mDC) (Table 52.2); neither population expresses co-stimulatory molecules. In contrast, synovial fluid and tissue mDC subsets resemble mature peripheral blood cells, but in addition a subset expresses high levels of CD86 and can support allogeneic mixed leukocyte reactions

(Table 52.2). More recent data indicate that they may differentiate further *in situ*, as suggested by nuclear translocation of RelB in perivascular DC infiltrates, consistent with prior cytokine receptor or TLR engagement *in vivo*. Perivascular RA synovium also contains populations of HLA-DR⁺CD11c⁻CD123⁺ plasmacytoid DC (pDC); in contrast to the myeloid DC subset, these are RelB⁻ and comprise ~ 30% of all synovial DC. A subset of pDC express BDCA2 and may be capable of producing

Fig. 52.3 Cytokine networks in RA. The pathogenesis of RA can be thought of as a series of complex and closely related pathways regulated both temporally and spatially. These include: (1) an acute insult that may trigger the disease, characterized by stimulation of fibroblast-like synoviocytes (FLS) by inflammatory stimuli and the generation of cytokines and chemokines that promote the migration and infiltration by cells of the innate immune system; (2) repeated episodes of antigen-specific adaptive immune responses (in lymph node, bone marrow as well as in situ). Failure to resolve adaptive immunity is a key checkpoint which may lead to (3), a cytokine-driven chronic inflammatory phase where multiple cellular and molecular components sustain the response. Through multiple pathways acting on many cell types, this process leads to tissue injury. Proinflammatory pathways are shown in blue (text) and red (arrows), and anti-inflammatory, counter-regulatory pathways are shown in black (text and arrows). FLS, fibroblast-like synoviocytes; DC, dendritic cell; T_{eff}, effector T-helper cell; TCR, T-cell antigen receptor; Treg, regulatory T cell; B, B cell; AutoAb, autoantibodies; Mφ, macrophage; Adipo, adipocyte.

IFN- α *in situ*. Unlike their peripheral blood counterparts, synovial pDC efficiently activate allogeneic T cells to proliferate, as well as to produce IFN- γ , TNF- α and IL-10. Thus, many cellular and molecular components exist in RA synovium that could both initiate and serve to perpetuate the immune inflammatory response.

This initial wave of inflammation has two major consequences. First, inflammatory cytokines will promote the activation of vascular endothelium, changes that occur very early in disease (see above and Fig. 52.3). Under the influence of locally generated cytokines synovial postcapillary venules undergo morphological changes to an extent that they resemble high endothelial venules similar to those observed in secondary lymphoid organs. The second major consequence is the migration of inflammatory leukocytes, including polymorphonuclear leukocytes and immature or undifferentiated monocytes. This is possible because of chemokines produced on the one hand by resident stromal as well as infiltrating cells (Fig.

52.3), including IL-8/CXCL8, RANTES/CCL5, MIP-1 α /CCL3, SDF-1/CXCL12, IP-10/CXCL10, and MCP-1/CCL2,²⁷ and the upregulation on endothelium of cell surface adhesion molecules, including intracellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1) and E-selectin.¹⁹ C-X-C, C-C, C and C-X₃-C chemokines all play a role, exerting chemotactic activity towards neutrophils, lymphocytes and monocytes, but also influencing the topology of inflammatory infiltrates, as discussed above. They are invariably early activation genes, in response to inflammatory stimuli. In synovial joints, macrophages are probably the dominant source of such factors. Crucially, the expression of chemokine receptors such as CCR4, CCR5, CXCR3 and CX3CR1 on inflammatory cell subsets will contribute to the selectivity of cellular recruitment (Table 52.2).²⁷ These events characterize the acute phase of an innate immune response, a key checkpoint that precedes the progression to subsequent events that herald the onset of the chronic inflammatory phase.

AUTOANTIGENS IN RA

Although current models of adaptive immune responses would suggest that DC carry antigens derived from damaged or dying synovial tissue, the molecular nature of disease-associated antigens has, until recently, remained an enigma. Many RA-associated autoantigens have been described (Table 52.3). Other candidate autoantigens have been vigorously validated in animal models.²⁸ The best described are collagen II, HCgp-39, and more recently glucose-6 phosphate isomerase. However, when used as recombinant antigens none of these have been found to elicit reproducible and/or robust T- or B-cell responses in a significant proportion of patients. There are several plausible explanations for this. The most obvious are that antigens that drive autoimmune arthritis are not the same in mice and humans, or that detectable T-cell responses occur very early and are blunted in established disease. Another possibility is that the autoantigens used to test lymphocyte reactivity *in vitro* do not carry the post-translational modifications (i.e., the neo-epitopes) recognized by autoantibody or antigen receptor. Good examples are the carbohydrate moieties of collagen II epitopes that serve as key TCR contacts in collagen II immunity, and the citrullination of key arginine residues in triple helical CII peptides that appear to be the immunodominant autoantibody epitopes.

GENERATION OF NEOEPITOPES BY DEIMINATION

In 1998, van Venrooij and colleagues²⁹ first reported that patients with RA carried antibodies that recognized deiminated peptides of fillagrin, the substrate that was found to be the antigen recognized in rat keratinized epithelium. This substrate formed the basis of the anti-perinuclear factor (APF) assay. Using new generation anti-cyclic citrullinated peptide (anti-CCP)-based assays, the presence of these antibodies, now collectively termed anti-citrullinated protein antigens, have now been shown by many groups to be both sensitive (up to 80%) and highly specific (> 95%) for the diagnosis of RA.²⁹ Indeed, serum anti-CCP levels are stable with disease, they have been detected as early as 14 years prior to disease onset, and have been shown to be predictors of radiographic progression. Citrullination is not specific for RA (Fig. 52.4). Indeed, citrullination may be inflammation specific, as it has been documented in inflamed synovium derived from patients with reactive arthritis and psoriatic arthritis as well as RA, but not OA. What appears specific for RA is the immune response to citrulline (Fig. 52.4). A link between anti-CCP and HLA-DRB1 alleles, specifically SE⁺ alleles, has now been established.¹⁷ Linkage analysis across chromosome 6 has documented a large peak, with LOD scores of >10 for anti-CCP⁺ patients but not for those who do

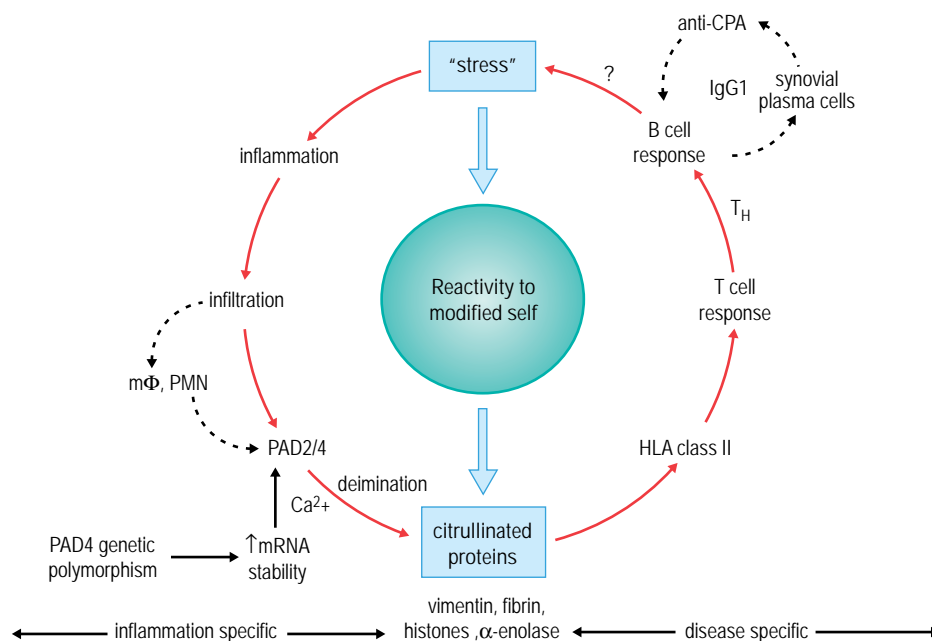

Fig. 52.4 The generation of autoantibodies to citrullinated protein antigens. The stressed and inflamed synovium is characterized by an influx of inflammatory cells, including macrophages and neutrophils that express peptidyl-arginine deiminases (PAD). In the presence of sufficient $[Ca^{2+}]$, PADs deiminate target proteins, including, among others, vimentin, fibrin, histones and α -enolase. This is inflammation, but not disease specific. The combination of environmental stimuli (including inflammation and tobacco smoke) and the inheritance of specific HLA-DRB1 alleles favor T- and B-cell immune responses to the host's derivatized neo-epitope peptide antigens. Th, T-helper effector cell; anti-CPA, autoantibodies to citrullinated protein antigens.

not carry these antibodies. This relationship is independent of RF status, as the SE allele frequencies in anti-CCP⁺ patients are twice those of anti-CCP⁻ patients, even those who are RF⁺. Indeed, the risk of carrying SE in RF⁺anti-CCP⁻ patients is no different from that in the healthy control population. These data would be consistent with a model where T cells from patients with RA can recognize peptide autoantigens modified by citrullination if they carry SE⁺ DRB1 alleles. Studies in HLA class II transgenic mice suggest that the conversion of positively charged arginine at key residues in antigenic peptides from candidate autoantigens to neutral citrulline is permissive for peptide binding and the induction of antigen-specific immune responses *in vivo*.

Finally, citrullination is widespread in multiple tissues in response to appropriate provocations. Although the molecular basis for these triggers is poorly understood, recent data point to a link between smoking, an environmental exposure known to be linked with RA, citrullination, and individuals carrying SE.³⁰ Thus, cells derived from bronchoalveolar lavage from smokers express citrulline, but not those from nonsmokers. The association between the development of RA and smoking has now been linked to anti-CCP⁺ patients, whose relative risk increases to 20 if they smoke and carry two copies of the SE⁺ DRB1 alleles, compared to patients with anti-CCP⁻ disease showing much weaker or no such relationship. These data may have clinical significance; at the outset of disease, they may provide useful predictors of patients who are more likely to progress to develop severe erosive joint disease.

LYMPHOCYTE BIOLOGY

Flow cytometric analysis of dissociated synovial mononuclear cell cultures indicates that infiltrating T lymphocytes can make up approximately 10–35% of cells in inflamed tissue. The ratio of CD4 to CD8 T cells seen in peripheral blood is skewed in favor of the CD4 subset. Much of the information on phenotype and function is derived from detailed analyses of synovial fluid, and, to a lesser extent, synovial tissue subsets (Table 52.2). Similar enrichment of these subsets is commonly detected in PBL. The majority of synovial T cells express phenotypic markers of antigen-experienced, terminally differentiated T cells with enhanced migratory capacity. Thus synovial T cells would typically be cell surface HLA-DR⁺, LFA-1⁺, VLA-1⁺, CD69⁺, CD45RO⁺, CD45RA⁻, CD45RB^{dim}, CD29^{bright}, CD27⁻, CD25⁻ (Table 52.2).³¹ Synovial B cells also express a typical memory/differentiated phenotype. Indeed, analysis of the variable regions of the Ig heavy and light chains confirms that antigen-specific activation and differentiation of B cells into plasma cells takes place in the chronically inflamed synovial tissue of patients with RA. Analysis of synovial T cells reveals that expression of the TCR invariant chain subunits CD3 ϵ and TCR ζ are found at lower density than that found in corresponding peripheral blood T cells, consistent with evidence of prior antigen engagement. Although synovial fluid T cells are also FasL⁺, Bcl2⁻, Bax^{bright}, favoring a pro-apoptotic state, it is thought that environmental cues transduced through common γ -chain receptor signaling cytokines such as IL-2, IL-7 and IL-15, as well as type I interferons, prevent apoptosis of T cells *in situ*.³² Synovial

tissue-derived lymphocytes may be different. Consistent with their state of terminal differentiation, synovial T cells comprise populations of T cells with a contracted oligoclonal repertoire, based on assessment of TCR gene rearrangements.²² A subset of these cells are CD28^{null}, while at the same time expressing a range of NK-cell surface receptors that are thought to contribute to effector function independently of cognate antigen.²² Nevertheless, to date there exists no common TCRVB family that might suggest expansion of such clones by a common RA-specific antigen. A subset of IFN- γ -producing CD56^{bright}TCR γ ^{neg} NK cells also appears to accumulate in RA synovial joints.

This state of terminal differentiation or immunosenescence of lymphocytes has several consequences.^{6,33} First, synovial T cells are hyporesponsive to TCR ligation. This may directly reflect a state of proliferative exhaustion, exacerbated by the effects of the inflammatory milieu, including cytokines, reactive oxygen intermediates, and depletion of essential nutrients such as tryptophan or arginine, which target the expression and function of key TCR proximal signaling molecules, including TCR ζ , p36 LAT and small GTP-binding molecules, all of which play a specialized role in transmitting signals from the antigen receptor to downstream signaling pathways. Second, these defects may also be detected in the periphery, manifesting themselves as a state of 'anergy,' with impaired DTH skin tests. It is also possible that this state of hyporesponsiveness contributes to the twofold enhanced susceptibility to infection (skin, joint and respiratory tract), especially in patients with more severe disease. Third, the profile of cytokines in SF from patients with very early RA suggests evidence of early Th2 differentiation (arising perhaps from a mast cell-derived IL-4 environment), this profile changes rapidly as the inflammatory process evolves, as synovial T cells from patients with established disease express barely detectable levels of T cell-derived cytokines, including IL-2, IL-4, IL-5 and IL-13, and only small subsets express IFN- γ , some of which also express IL-10. This finding has formed the principle argument against T cells playing a role in established disease. Nevertheless, the finding of reproducible levels of IFN- γ by a subset of synovial T cells has implied a bias toward a Th1 response. The contribution of IL-17 expressing T cells is not clear.

MOLECULAR BASIS OF PERSISTENCE

Understanding the molecular basis of persistence is of major importance in diseases such as RA. Whereas inflammatory infiltrates persist in patients with active disease, the local synovial stromal microenvironment provides a unique niche for the development of follicular lymphoid microstructures in a subset of patients.³⁴ As mentioned above, these are stable over time and are found in multiple joints from the same patient. For their persistence these structures have been shown to be associated with the expression of LT β , LT β R and the chemokines CCL19 and CCL21.³⁵ LT β is expressed on activated T and B cells, and the rather more restricted expression of LT β R is confined to synovial stromal cells. The importance of LT β -LT β R signaling, which utilizes both canonical (IKK β /IKK2) and alternative (IKK α /IKK1) pathways of NF- κ B activation, has been firmly established in LT β - and LT β R-deficient mice, which exhibit severe defects in lymphoid organogenesis. The tumor repressor p53 and PTEN may also contribute to the survival of synovial stroma. It is not surprising, therefore, that these structures (which are associated with more severe, seropositive, erosive disease) also provide a local niche for B-cell differentiation and immunoglobulin production. Indeed, it has been shown that follicular B cells are a source of local autoantibody production, including

RF and anti-CCP. B cells can also contribute to antigen-presenting functions,³⁶ as well as being a major source of chemokines and inflammatory cytokines, including IL-6. The direct contribution of immune complexes to local inflammation and tissue destruction has long been implied, mediated in part through engagement of activating FcR.³⁷ Nevertheless, local complement consumption in the synovium has long been recognized, and evidence from the KRN serum transfer arthritis model suggests that local deficiency of naturally occurring inhibitors of complement activation may contribute to the tissue specificity of the inflammatory response.

It is now well established that enhanced expression of inflammatory cytokines is one of the hallmarks of chronic inflammatory diseases such as RA.³⁸ With few exceptions, most cytokines are expressed in inflamed synovium at mRNA or protein levels. For example, unlike PBL from healthy donors, explants of synovial mononuclear cells constitutively express IL-1, IL-6, IL-8, GM-CSF and a vast array of chemokines, as well as growth factors, including FGF, VEGF and PDGF (Fig. 52.3). Although anti-inflammatory or immunoregulatory cytokines, including IL-4, IL-10, IL-11, TGF- β and specific naturally occurring inhibitors of IL-1 α / β (IL-1Ra) and TNF- α (soluble TNF-R) may also be detected, functional bioassays suggest that the overriding response is inflammatory. Indeed, levels of IL-1Ra and sTNF-R are significantly upregulated in synovial fluid compared to serum from patients with RA. Yet IL-1 and TNF bioactivity persists in spite of this, suggesting that attempts to suppress cytokine activity are insufficient. The specific activity of subsets of cytokines, their networks, and how they may contribute to RA is illustrated in Figure 52.3. In many cases, the pathogenic roles of cytokines have been established in rodent models, either by selectively blocking their function (e.g. with specific monoclonal antibodies or soluble receptor fusion proteins) or by gene targeting approaches. Perhaps the best documented include the inflammatory arthritides documented in transgenic mice over-expressing human TNF- α , in IL-6 signaling gp130 mutant mice and ZAP-70 mutant SKG mice.³⁹ Disruption of immunoregulatory or inhibitory cytokines, including IL-1ra, IL-10 and TGF- β , leads to severe auto-inflammatory syndromes targeting different organs, depending on genotype.

A major challenge has been to identify the pathways that promote chronic cytokine and chemokine expression *in vivo*. One possible mechanism is that of cell contact-dependent stimulation of macrophages and fibroblasts by activated T cells (Fig. 52.3).⁴⁰ This is an appealing pathway, given that T cell-derived products such as IFN- γ that prime macrophages to produce TNF, IL-1 and IL-6 are relatively deficient in inflamed synovium. Physical contact of activated but not resting T cells induces abundant TNF- α , IL-1 β , IL-8, MCP-1 and MMP production by monocytes (Fig. 52.3). This can be reproduced using T-cell plasma membrane preparations, and prevented by interrupting cell contact. Interestingly, the effector response depends on the nature of the T-cell stimulus. Thus, Th2 T cells produce relatively more monocyte-dependent IL-1Ra than IL-1 β and higher ratios of TIMP than MMP. Contact between T cells and synovial fibroblasts has also been shown to induce IL-6, MMPs and PGE₂ (Fig. 52.3), each of which may contribute to distinct aspects of downstream effector pathways.

IMMUNE REGULATION

The recent emergence of interest in regulatory cell subsets and their anti-inflammatory properties has perhaps more firmly established the concept that failure of the default mechanisms of immune regulation may underpin autoimmune diseases. Experiments in gene-deficient mice

(e.g., Foxp3, IL-2, IL-2R, IL-2R signaling, STAT5, IL-10, TGF- β) lend support to this concept. In RA the data remain less clear.⁴¹ For example, there is *in vitro* evidence for a relative deficiency of constitutive IL-10 expression in synovial cell cultures, and yet clinical trials of IL-10 were rather disappointing; TGF- β is yet to be tested. These results may reflect the complex role of these cytokines in disease pathogenesis. The identification of defective numbers and/or function of CD4⁺CD25^{bright} regulatory T cells (Tregs) has been suggested by several investigators, but reports are conflicting. Some studies have shown a clear reduction in the numbers of peripheral blood Tregs in patients with RA, but others have shown no difference; interestingly, Tregs appear deficient in numbers in subsets of children with juvenile idiopathic arthritis (JIA) whose disease tends to progress. In synovial joints the data are more consistent, with many reports showing substantial increases in Treg numbers in synovial tissue and fluid compared to paired peripheral blood. However, some studies have reported normal function at a cellular level, whereas others have shown depressed regulatory function.

Two recent reports which both studied Treg phenotype and function in patients receiving anti-TNF therapy have provided some insight into the relationship between inflammation and defective regulatory function. Ehrenstein and colleagues⁴² demonstrated that whereas PB Tregs from patients with active RA could suppress the proliferation of CD4⁺CD25⁻ effector T cells, they failed to suppress IFN- γ and TNF- α production. Treatment with infliximab reversed this defect, but also conferred the capacity of CD4⁺CD25⁻ precursors to become regulatory cell subsets. A second study demonstrated that TNF at high doses suppresses the expression of Foxp3,⁴³ a helix-loop-helix transcription factor family member whose deficiency causes Scurfy disease and IPEX in mice and humans, respectively, and is expressed relatively selectively in Tregs (more specific for mouse than human Tregs). In this study, infliximab treatment restored Foxp3 expression in PBL. The data provide a crucial link between inflammation and failure of immune regulation, and may go some way to explain the immunomodulatory properties and sustained clinical benefit of anti-TNF, not only in RA but in a wide range of other chronic inflammatory diseases.

IMPACT OF THE IMMUNE RESPONSE ON CARTILAGE AND BONE

For many years it was thought that the terminal effector phase of chronic inflammation that led to cartilage destruction and bone resorption was driven almost exclusively by inflammatory cytokines and proteinases. IL-1, MMPs (MMP1, 3, 8, 13) and more recently aggrecanases (ADAMTS 4 and 5) were and remain the major culprits. Attempts to establish more directly a link between adaptive immunity and destruction of target tissue failed, not least because of the lack of direct contact between lymphocytes, chondrocytes and bone. A breakthrough came in the late 1990s with the identification of the TNF/TNF-R family member receptor for activation of NF- κ B ligand (RANKL)/TRANCE/ODF and its counter-receptor RANK, and the dissection of the molecular and cellular components required for differentiation of osteoclasts from monocyte precursors.⁴⁴ According to contemporary paradigms, RANKL is necessary and sufficient for osteoclast differentiation. TNF, M-CSF and IL-17 probably contribute, and RANKL-independent pathways may also play a role. RANKL is expressed on synovial fibroblasts and osteoblasts, but also on activated T cells, its counter-receptor being expressed on myeloid lineage cells including monocytes, osteoclast

precursors and dendritic cells. Its expression is regulated by inflammatory mediators including TNF and PGE₂. RANKL is shed, probably through the action of several membrane-associated proteases, including MT1-MMP (MMP14). Gene targeting of RANKL or RANK in mice leads to inhibition of osteoclastogenesis and a profound osteoporotic bone phenotype. Deletion of OPG, the naturally occurring decoy soluble receptor for RANK, leads to unbridled osteoclast differentiation and bone resorption, and substantially reduced bone mass. A good example of the link between adaptive immunity and bone resorption comes from CTLA4^{-/-} mice, characterized by sustained chronic T-cell activation.⁴⁵ T cells from these mice over-express RANKL. Importantly, the bone, but not the inflammatory phenotype, is rescued by inhibition of RANK/RANKL signaling. In RA, several studies have demonstrated perturbations of serum RANKL/OPG ratios, a parameter currently under investigation as a biomarker for bone homeostasis.

CLINICAL FEATURES

DISEASE ONSET

RA is a heterogeneous disease that does not conform to a single clinical entity.² Whereas 10% of patients may have an acute severe onset and 20% a more subacute onset, in up to 70% of patients the onset of signs and symptoms may be insidious. A more episodic or palindromic onset has also been described. A common presentation, more likely during the winter months, is that of a female in the fourth to fifth decades of life who complains of diffuse symmetrical joint pain, swelling and stiffness of small peripheral joints. Patients frequently complain that they can no longer make a fist, especially in the early morning. The targeting of afflicted synovial joints may be symmetrical in most cases, typically affecting the small joints of the hands and feet, as well as the wrists. Less frequent are those with slow-onset monoarticular disease. Patients not fulfilling the diagnostic classification criteria for RA (see below) may, at this point, be ascribed the more appropriate diagnostic label of undifferentiated arthritis, as in a proportion of cases signs and symptoms may resolve spontaneously. At 1 year approximately 30% will progress to develop the syndrome we call RA.

ARTICULAR SIGNS AND SYMPTOMS

Systematic examination of the musculoskeletal system and careful documentation of the pattern of joint involvement (e.g., symmetry, axial versus peripheral joint involvement) are crucial to establishing an unambiguous clinical diagnosis of RA. Patients will often present with swelling, in addition to pain, which affects the whole surface of small joints, in contrast to weightbearing joints. Swelling may arise as a consequence of the disease process affecting intra-articular structures, typically presenting with soft tissue swelling and joint fluid (demonstrated clinically by fluctuation), or periarticular structures including the joint capsule, which is very sensitive to stretching and distension. Tenderness and swelling most closely reflect the intensity of the inflammatory process, but erythema, more characteristic of crystal arthropathies or articular sepsis, is unusual. Surprisingly reliable indicators of the intensity of inflammation include early morning stiffness (as distinct from immobility stiffness), commonly occurring for more than 1 hour per day, poor grip strength, and pain on passive joint movement. In the absence of swelling of specific joints, pain elicited on lateral compression of metacarpophalangeal (MCP) or metatarsophalangeal (MTP) joints (the

MCP or MTP joint 'squeeze') is predictive not only of active disease but of progression to erosive disease. Less frequent are those patients presenting with inflammatory disease of other synovial structures in isolation, such as bursitis. The presence of flexor tenosynovitis at the outset is more common.

HANDS

There is a variety of well-recognized clinical signs that arise as a consequence of more progressive joint inflammation. This is prominent in both upper and lower limb peripheral joints. Symmetrical involvement of PIP joints may lead to fusiform swelling of the joints. Disease of associated structures, including tendons and synovial sheaths, commonly coexists, and together these contribute to impairment in grip strength, whereas distal interphalangeal (DIP) joint involvement is more likely to reflect coincidental osteoarthritis. Specific deficiencies in articular and periarticular structures may arise through variable effects of muscle atrophy, tendon laxity or shortening, tendon rupture, weakening of the joint capsule, and cartilage destruction where an imbalance of forces is transmitted across the joint. Classic joint deformities besides synovitis include joint subluxation, ulnar drift, Boutonnière's and swan-neck deformities; where the thumb is affected, flail, Boutonnière's or duck-bill deformities may develop. Often deformities may occur in combination, such as the subluxation that occurs at MCP joints associated with ulnar drift due to weakening of both dorsal and radial structures and lengthening of collateral ligaments.

WRISTS

Symmetrical involvement of the wrist is common, and loss of wrist extension is an early clinical sign. Typical signs include swelling over the ulnar styloid, whose prominence may be further exacerbated by a predilection for ulnar synovitis, supination-subluxation at the carpus, and disruption of the triangular ligament which promotes volar rotation. Subluxation predisposes to erosion of the floor of the extensor compartments, leading to extensor tendon rupture. Unrelenting progressive synovitis at the wrist may ultimately promote fibrosis and then bony ankylosis of the carpus.

ANKLES AND FEET

Hindfoot disease, leading to ankle, subtalar and talonavicular synovitis, is more common than is generally appreciated. Progressive pain, stiffness and peroneal muscle spasm often cause valgus deformity, which increases as cartilage destruction and bone erosion develop. This invariably leaves the patient with a spastic flat foot as flattening of the longitudinal arch progresses. Spontaneous fusion is not uncommon. Disease of the metatarsal heads associated with synovitis of the metatarsophalangeal joints and flexor tenosynovitis is classic, and in very early disease tenderness in response to lateral compression of MTP joints is predictive of progressive, erosive disease.

INVOLVEMENT OF LARGE JOINTS

Although disease of the large joints is well documented they may be spared, especially at the onset and during the early phase of disease. Synovitis of the elbow is a useful sign as it occurs much less frequently in other inflammatory arthritides. The earliest sign is loss of full extension, which may not

influence function to any great extent. As disease progresses, the humeroulnar joint is the first to develop erosive changes. With advanced disease this may herald proximal movement of the radial head. Once this affects elbow flexion function is invariably compromised, as supination may also become restricted. RA of the shoulder is observed in more progressive disease and may not become symptomatic or affect day-to-day function until the joint disease is more advanced. Erosive synovitis may target not only the humeral head or glenoid fossa, but also the acromioclavicular joint.

Large joint disease affecting the lower limbs occurs more commonly in the knees than the hips. Whereas the hip may be spared at the outset, hip disease can present with groin discomfort and abnormal gait. Range of movement at this joint may become compromised once synovitis has induced loss of cartilage. As the inflammatory process progresses erosive disease will lead to protrusion of the acetabula. Osteonecrosis is relatively common at the hip, and may arise more often in those patients exposed to long-term corticosteroid therapy. Knee disease is more obvious and can present as small yet obvious effusions (elicited through the 'bulge sign'), and then fixed flexion deformities and popliteal fullness (progressing to Baker's cyst). With active, chronic synovitis progression to erosion and loss of articular cartilage is almost inevitable. At this stage, laxity of collateral or cruciate ligaments further promotes joint instability, detected clinically by lateral or medial movement of the distal limb against the femur, or by the 'draw sign,' respectively. Depending on loading, these deformities may progress to valgus or, less commonly, varus deformities.

DISEASE OF OTHER JOINTS AND TISSUES

Disease of other synovial structures such as the temporomandibular and cricoarytenoid joints is well documented though relatively rare, as is involvement of the ossicles of the ear. Disease of the axial skeleton is restricted to diarthrodial joints of the upper cervical spine (C1–C2). In the early phase this may present with little in the way of pain, but with restriction of movement, especially in lateral flexion, stiffness, and a sensation of 'clunking' at extremes of movement. Synovitis of the articulation between the transverse ligament of the atlas and the posterior aspect of the odontoid peg compromises the transverse ligament allowing forward slip of the atlas (C1) on the axis (C2; atlantoaxial subluxation). The dens may also erode. With severe unremitting synovitis encroachment onto the apophyseal joints may permit basilar invagination of the odontoid into the foramen magnum, threatening both upper cervical cord and the medullary structures. This is potentially life-threatening and poses a significant pre- and perioperative anesthetic risk. Synovitis of the dorsolumbar spine is confined to the apophyseal joints, which, when the synovium is hypertrophied, can lead to compromise of the cord or nerve roots; in the lower lumbar spine this may present with typical signs of lumbar canal stenosis. It should be noted that through different mechanisms, chronic inflammatory diseases such as RA are associated with accelerated loss of bone mass, and bone mineral density may be rapidly compromised further in those patients taking corticosteroids.

SYSTEMIC AND EXTRA-ARTICULAR MANIFESTATIONS

In addition to generalized polyarthralgia and/or myalgia, common associated signs and symptoms can include systemic features such as anorexia, weight loss or low-grade fever. Fatigue is a particularly good indicator of systemic inflammation but is hard to quantify clinically, being reflected

Table 52.4 Systemic and extra-articular features of RA

General Fever, sweats Lymphadenopathy Weight loss Fatigue, weakness	Neurological Myelopathy Entrapment neuropathy Peripheral neuropathy Mononeuritis multiplex
Dermatological Palmar erythema Subcutaneous nodules Vasculitis Ulceration, neutrophilic dermatoses	Haematological Anemia Thrombocytosis Lymphocytosis or lymphopenia Felty's syndrome Large granular lymphocytes Lymphoproliferative disease
Ophthalmic Episcleritis Scleritis Choroid and retinal nodules Keratoconjunctivitis sicca	Renal Interstitial nephritis Renal tubular acidosis Amyloidosis
Pulmonary Pleuritis Nodules Interstitial pneumonitis Bronchiolitis obliterans Arteritis Pulmonary hypertension	Gastrointestinal Xerostomia Transaminitis NSAID enteropathy
Cardiac Pericarditis Myocarditis Coronary vasculitis Atheromatous disease Valvular nodulosis	Musculoskeletal Myositis, muscle weakness Osteoporosis

more by levels of inactivity or failure to undertake routine daily activities. Other manifestations are more obvious and are listed in Table 52.4.

NATURAL HISTORY, CLINICAL COURSE AND PROGNOSTIC FACTORS ASSOCIATED WITH DISEASE PROGRESSION

Many studies have attempted to identify clinical variables relating to disease onset, or its initial progression, that reproducibly predict patterns of long-term outcome. It is generally agreed that gender, disease activity and functional status at onset, the use of early disease-modifying antirheumatic drugs (DMARDs) and tight control most consistently influence outcome. For those patients with established RA, Wolfe and Cathey^{45a} have applied the Stanford Health Assessment Questionnaire

CLINICAL PEARLS

PREDICTORS OF POOR OUTCOME IN RA

- >> Chronic, unremitting disease onset, especially at advanced age
- >> Female gender
- >> Poor functional status determined by validated functional disability indices such as the Stanford Health Assessment Questionnaire (HAQ) and the Arthritis Impact Measurement Scale (AIMS)
- >> Low socioeconomic status
- >> Systemic and extra-articular features
- >> Comorbidity, e.g., infection, cardiovascular disease, renal impairment
- >> Early erosive disease (in first 6–12 months, often associated with anti-CPA autoantibodies)
- >> Persistent acute-phase response (e.g., time integrated CRP levels)
- >> Autoantibodies (RF and anti-CPA) and HLA-DRB1 status (SE⁺)
- >> Significant delay in early use of DMARD and corticosteroids

CPA, citrullinated protein antigens; CRP, C-reactive protein; RF, rheumatoid factor; SE, shared epitope; DMARD, disease-modifying antirheumatic drug.

(HAQ) and Functional Disability Index (FDI) in 1274 RA patients followed for 12 years to demonstrate that the progression of disability is most rapid in the first few years after onset. Loss of function was severe over 2–6 years and very severe by 10 years. Progression was found to be more rapid in older women, especially those with longer disease duration, as well as patients with poor grip strength, more pain, and higher global severity scores. Extra-articular and systemic features were also associated with greater functional loss. Simpler composite scores comprising grip strength, button test and walking time produced comparable results. These parameters also predicted longevity, translating to a twofold increase in standardized mortality rates in those patients with severe disease, equivalent to Hodgkin's lymphoma or triple-vessel coronary artery disease. Indeed 5-year survival rates in patients with severe RA have been estimated to be between 40% and 50%. Comorbidity and increased mortality may be related directly to cardiovascular disease associated with chronic inflammation, increased susceptibility to infection, and gastrointestinal adverse events.

DIAGNOSIS

CLASSIFICATION CRITERIA

The American College of Rheumatology criteria for the classification of RA are a set of clinical and laboratory parameters that serve as a guide for the diagnosis of RA, and were established largely for epidemiological purposes. They are relatively straightforward and easy to apply, especially to patients with established disease. However, failure of a patient with early signs and symptoms of an inflammatory arthropathy to fulfill

Table 52.5 1987 revised criteria for the classification of RA

1. Stiffness in and around the joints lasting 1 hour before maximal improvement
2. Soft tissue swelling (arthritis) of 3 or more joint areas, simultaneously, observed by a physician
3. Swelling (arthritis) of the proximal interphalangeal, metacarpophalangeal, or wrist joints
4. Symmetric swelling (arthritis)
5. Rheumatoid nodules
6. The presence of rheumatoid factor
7. Radiographic erosions and/or periarticular osteopenia in hand and/or wrist joints
 - four of seven criteria are required to classify a patient as having RA
 - criteria 1–4 must be present for at least 6 weeks
 - criteria 2–5 must be observed by a physician

them does not mean that she or he does not have RA. The revised 1987 criteria have been further simplified by removing the ‘probable,’ ‘definite’ and ‘classic’ subclassifications (Table 52.5).⁴⁶ These new criteria have a sensitivity for RA of 91–94% and a specificity of 89% in the clinical setting. Although these 1987 criteria are used regularly in clinical practice and research, it is likely that as subgroups of patients become defined based on molecular parameters that are clinically meaningful in terms of prognosis and therapy, the criteria may become more sophisticated; stratification of disease according to anti-CCP status is one good example.

LABORATORY FINDINGS

Routine laboratory hematologic and biochemical anomalies, such as normochromic, normocytic anemia, thrombocytosis, and perturbations in the leukocyte count, may inform disease activity but are neither specific nor helpful in diagnosis. The same can be said of the myriad acute-phase proteins, in addition to the ESR, including CRP, fibrinogen, α -macroglobulin, serum amyloid protein and ferritin, although their levels may provide a useful indication of disease activity and longer-term prognosis when measured over time. As with serum biomarkers, analysis of synovial fluid, although undertaken quite frequently in the clinical setting, is rarely, if ever, diagnostic. A typical RA synovial fluid exudate may be turbid due to cellularity ($> 50\,000/\text{mm}^3$, although more typically in the $20\text{--}40\,000/\text{mm}^3$ range) and contain abundant PMNs, with reduced viscosity. Invariably, the exclusion of sepsis or crystals is most useful with respect to SF analysis.

Until the late 1990s, IgM rheumatoid factors (RF) – autoantibodies that recognize the Fc subunit of IgG – remained one of the few parameters of value in the clinical setting, forming the basis of the seropositive versus seronegative stratification of RA, and identifying those patients more likely to progress to erosive disease with or without extra-articular features.⁴⁷ Nevertheless, RF can be detected in up to 5% of the healthy population and between 10% and 20% of the aging population (> 65

years of age), and is found in a range of rheumatic conditions, including Sjögren's syndrome, SLE, and cryoglobulinemia, as well as in acute infectious and neoplastic disease entities, influencing its diagnostic utility. In general RF is not of value for monitoring responses to therapy.

The discovery of antibodies to cyclic citrullinated antigens (anti-CPA) is likely to change diagnostic practice once the assays become more widely available, not least because they are found very early in disease.²⁹ They also have prognostic value in terms of radiographic progression. The new generation of anti-CCP kits has demonstrated a diagnostic sensitivity of 80% and a specificity of 98%. It is likely that as the range of RA-associated autoantigens expands, and as the repertoire of deiminated target autoantigens is defined, multiplex assay of serum autoantibodies will play an increasingly important role in the diagnosis and prognosis of subsets of inflammatory arthritides. Other biomarkers used in either clinical or investigative settings are listed in Box 52.3.

IMAGING

Plain radiographs of the hands and feet are rarely useful during the first 6–12 months of disease other than to confirm soft tissue swelling, which is invariably present on clinical examination. Nevertheless, they provide an important baseline against which to compare subsequent studies. Beyond this time, abnormalities may include periarticular osteopenia, cortical breaks, loss of articular cartilage (manifest as joint space narrowing) and early bone erosions, especially at the head of metacarpals and metatarsals, or at the base of proximal phalanges (Fig. 52.5). Late changes include subluxation, and eventually bony destruction and ankylosis. High-resolution ultrasound (HRUS) has gained much support, especially as it is cheap and possible to use at the bedside. In combination with power color Doppler imaging modalities, which detect vascularity in addition to inflammation, HRUS has proved to be superior to plain radiographs in detecting early cortical erosions (which require confirmation in longitudinal and transverse planes). It is also useful for detecting subclinical tenosynovitis. Although not all joints are accessible, HRUS has proved especially useful for the monitoring of MCP joints and wrist disease. More expensive, but more sensitive still, is magnetic resonance imaging (MRI), which can detect erosions and bone marrow edema at very early stages of disease, as well as defining periarticular structures, which are more selectively involved in the seronegative arthropathies.

TREATMENT

Contemporary management of patients with RA requires a multidisciplinary approach, with emphasis on reduction of pain, suppression of inflammation and restoration of function.² This is possible only through a coordinated input from a team comprising physician, physiotherapist, occupational therapist, psychologist and surgeon. In current practice, suppression of inflammation is a realistic goal with aggressive and intensive therapy and monitoring. The immunological goal is to halt the underlying disease process by restoring immune homeostatic mechanisms, but this has yet to be achieved routinely in humans.

DISEASE MODIFYING ANTI-RHEUMATIC DRUGS

Over the last two decades there has been a dramatic paradigm shift in the therapy of RA from control of symptoms to the control of the disease process.⁴⁸ This has come about through a growing appreciation of the

relationship between joint inflammation and joint destruction, and the development of imaging technology that has documented evidence of erosive changes within the first 6–12 months of disease. The impact of this paradigm shift in therapeutic terms is striking. Traditional 'go-low, go-slow' regimens of the 1970s and 1980s included the initiation of nonsteroidal anti-inflammatory drugs (NSAIDs), followed by implementation of disease-modifying anti-rheumatic drugs only after destructive disease became evident. Depending on the clinical response, sequential monotherapy was the norm. Although this strategy may still be appropriate for patients with mild disease, current practice now dictates aggressive combination therapy (two or more conventional DMARDs) from the outset for patients with poor prognostic factors, with preference for the faster-acting DMARDs such as methotrexate, leflunomide and sulfasalazine (onset 3–6 weeks) over slower-acting agents, hydroxychloroquine, gold and D-penicillamine (onset 3–6 months), but with the addition of low-dose prednisolone (<10 mg/day). The rationale for combination therapy is far from clear and

has yet to be established in well-designed clinical trials, but could relate to the targeting of distinct pathogenic pathways by different agents, a strategy favored by oncologists for decades. Corticosteroids have a major place in clinical practice when administered as a single intramuscular injection, either as therapy for disease flares, as bridging therapy until DMARDs take effect, or when administered as an intra-articular injection to treat isolated joint synovitis. Some regimens favor high initial dose stepdown corticosteroid protocols. Regardless of the route of administration, evidence points to the value of corticosteroid use early in the disease process. Alternative DMARDs such as cyclosporine A, azathioprine and leflunomide are valuable adjuncts, but used less often as first-line therapy in some countries. Regardless of the specific agent, meta-analyses have demonstrated better response and retention rates when multiple DMARDs are used early. Adverse events are no more frequent with combination therapy. More recent data suggest that the specific choice of therapy may be less important than the strategy. For example, the TICORA and BeST studies^{49, 50} both

Fig. 52.5 The spectrum of disease severity in RA (**A** and **B**) Chronic, severe and erosive RA showing joint swelling and classic deformities. indicate that intensive treatment combined with intensive control most convincingly influences outcome measures, including clinical response, retention, functional status and radiographic progression.

THE IMMUNOBIOLOGY OF DMARD THERAPY

The traditional paradigm of antigen-driven lymphocyte effector responses in RA promoted the application of a range of immunosuppressive drugs for treatment of the disease.⁴⁸ These contrast with more anti-inflammatory DMARDs, such as sulfasalazine (a scavenger of reactive oxygen intermediates with effects on prostanoid synthesis), gold (an inhibitor of AP-1 and NF- κ B transcription factor DNA binding and/or transcriptional activity),

D-penicillamine (a modulator of sulfhydryl groups with effects on surface receptor function, intracellular signaling and transcription factor binding), antimalarials (which perturb lysosome acidification and intracellular trafficking), and low-dose corticosteroids (with anti-inflammatory actions related to *trans*-activation and *trans*-repression of inflammatory gene expression as well as effects on inflammatory gene mRNA stability). The best-characterized immunosuppressive agents include methotrexate (a dihydrofolate reductase inhibitor that targets T cells and the production of inflammatory cytokines as well as IL-2), azathioprine (whose active metabolite, 6-mercaptopurine, suppresses lymphocyte proliferative and cytokine responses as well as immunoglobulin synthesis), cyclosporine A (an inhibitor of the phosphatase calcineurin and NFAT transcriptional activity) and

THERAPEUTIC PRINCIPLES

TREATMENT PARADIGMS IN RA

- >> Education and counselling through early involvement of multidisciplinary team, including a specialist nurse; appropriate balance of rest and exercise during disease flares
- >> Adequate nutrition (especially important with severe, active disease)
- >> Comprehensive assessment of disease activity, including imaging
- >> Aim for complete suppression of inflammation early in disease, with tight control through regular and frequent reassessments
- >> Early relief of pain with judicious use of NSAID or COX2 inhibitors according to safety/risk profile
- >> Early use of DMARD/SAARDs
- >> Early use of corticosteroids (e.g., low doses ~ 7.5 mg/day), including use of intra-articular injections to suppress inflammation
- >> Use of stepup combination therapy in severe disease
- >> Appropriate use of biologics, e.g., early use of anti-TNF in severe disease
- >> Monitoring for drug toxicity
- >> Effective contraception, where appropriate
- >> Bone protection
- >> Monitoring for risk factors of cardiovascular disease
- >> Vaccination (preferably before instituting immunosuppressive agents)

NSAID, nonsteroidal anti-inflammatory drug; COX, cyclo-oxygenase; DMARD, disease-modifying anti-rheumatic drug; SAARD, slow acting antirheumatic drugs.

leflunomide (an inhibitor of dihydro-orotate dehydrogenase that affects a rate-limiting step in de novo pyrimidine synthesis that inhibits lymphocyte proliferative responses, which may favor Th2 differentiation). Somewhat paradoxically, most of these DMARDs may restore the cell-mediated immune response under circumstances where there is robust suppression of inflammation. On the other hand, significant changes in autoantibody titers, especially rheumatoid factor (RF), are less frequently observed.

THE IMMUNOBIOLOGY OF BIOLOGICAL THERAPY

Anti-cytokine therapy

The introduction to the clinic of targeted therapy using biological agents (e.g., chimeric or fully humanized antibodies to ligands or receptors, soluble receptor fusion proteins, or recombinant receptor antagonists) has transformed the treatment of RA. The prototype is TNF- α blockade.⁵¹ The rationale for inhibiting TNF- α bioactivity is based upon its pleiotropic effects on cell activation, cellular adhesion and migration, induction of cytokine and inflammatory gene mRNA and protein, and the regulation

of cartilage catabolic factors such as IL-1 and matrix metalloproteinases (see Fig. 52.3). TNF- α and other inflammatory cytokines such as IL-1, IL-6, IL-15 and IL-17 are expressed constitutively in inflamed synovial tissue at mRNA and protein level. In many cases the expression of their high-affinity cognate receptors is upregulated and the functional activity of the corresponding naturally occurring inhibitors (e.g., soluble TNF-R or IL-1Ra) is reduced (although levels of protein may be increased, reflecting an attempt to restore homeostasis). As proof of principle, inhibition of cytokine activity, including that of TNF- α , IL-1, IL-6, IL-15 and IL-17, has been shown to have benefit in animal models of arthritis. Further, mice over-expressing hTNF- α as a transgene develop a spontaneous inflammatory destructive arthritis with 100% penetrance.

Chimeric anti-TNF monoclonal antibodies (infliximab; Remicade) were first used to treat RA in open-label clinical trials in 1992. Humanized antibodies (adalimumab; Humira) and the soluble p75 TNF-R IgG fusion protein (etanercept; Enbrel) were tested subsequently, with comparable therapeutic effects.⁵¹⁻⁵⁴ TNF- α blockade leads to dramatic and rapid reductions in the symptoms (pain, stiffness and fatigue) and signs (joint pain and swelling) of arthritis in a dose-dependent fashion, and in a significant proportion of patients (~ 60–70%) who have failed conventional DMARDs. These biological agents can be used repeatedly, and when used in combination with methotrexate are superior to either drug alone. The mechanism is not clear, but may be related to reductions in immunogenicity of the therapeutic antibody (i.e., the anti-chimeric antibody response), or perhaps the effects of combining anti-cytokine and anti-T-cell agents. Radiographic progression is attenuated over 2–3 years, even in subsets of patients with poor clinical responses, and in some patients radiographic scores improve, suggesting that healing of joint tissues may take place. TNF- α blockers when used early demonstrate superior remission rates. Some studies have shown that a significant proportion of patients remain in remission even after withdrawal of anti-TNF, possible evidence of immune modulation. The immunobiology of TNF- α *in vivo*, and its contribution to host defence, is further suggested by the increased incidence of upper respiratory tract, cutaneous and articular infections, and the significantly increased risk of reactivation of latent tuberculosis in patients treated with these agents. The risk of malignancy, particularly lymphoma, which is already increased in the RA population as a whole, does not appear to be increased with anti-TNF therapy. The development of antinuclear antibodies in 8–15% patients, as well as rare cases of demyelination, point to effects that may be related to restoration of immune responsiveness following TNF- α inhibition.

The clinical benefit of TNF- α blockade has prompted extensive mechanism of action studies which have been informative.⁵¹ Anti-TNF reduces the acute-phase response, including IL-6 serum levels. Leukocyte trafficking is inhibited, as demonstrated through an early (within hours) and dramatic rise in lymphocyte counts through demargination, a more prolonged and sustained exclusion of leukocytes based on reductions in cellularity of synovial tissue biopsies after treatment and suppression of markers of angiogenesis, including VEGF. The effects of anti-TNF treatment on cell viability and apoptosis remain controversial, however. TNF- α blockade has also been shown to downregulate markers of cartilage and bone destruction, including the collagenases MMP1 and 3, and to reduce the ratio of RANKL and OPG in serum, effects that might partly explain the joint-preserving effects of anti-TNF *in vivo*. Finally, there is additional evidence of anti-TNF-induced immune

homeostasis, based on restoration of cell-mediated immune responses to recall antigens and mitogens, but also an increase in both the numbers and function of CD4⁺CD25^{high} regulatory T cells, at least in some studies. This effect could be explained in part by the effect of TNF blockade on restoring the expression of the Treg-associated transcription factor FoxP3. Given that, at least in mice, IL-2 is a critical factor for maintaining Treg metabolic fitness, enhanced IL-2 production by effector T cells may contribute to immune homeostasis.

The IL-1 receptor antagonist (IL-1Ra) is the only IL-1 inhibitor currently licensed for use in RA.⁵⁵ It has good effects in animal models of arthritis, with potent joint protection, but has proved less effective in patients with RA compared to anti-TNF. Nevertheless, it has been used effectively to treat patients who have failed TNF- α blockade, and has been shown to slow radiographic progression. Blockade of IL-6 activity should be beneficial in RA because of the effects of IL-6 on the immune response, the acute-phase response, osteoclastogenesis, B-cell activation and immunoglobulin production, angiogenesis and cell adhesion. Indeed, anti-IL-6R has recently been proved in clinical trials to suppress the signs and symptoms of RA, with response rates comparable to those achieved with TNF blockade. However, the onset of disease suppression appears to be slower.

Anti-T-cell therapy

Although methotrexate, cyclosporine A and other immunosuppressive agents have claimed a place in the armamentarium for treating established RA, T cell-targeted therapeutic agents have been relatively disappointing as a group. Depleting anti-CD4 monoclonal antibodies were among the first specific agents to target this cell subset. Clinical efficacy was observed with responder rates consistently less than 30%, perhaps because of ineffective depletion of CD4 T cells in synovial joints, or because the antibody did not distinguish between T-cell effector and regulatory subsets. Theoretically, nondepleting anti-CD4 should be more effective, but this has yet to be confirmed in large phase III studies.

In contrast, the contribution of co-stimulatory signals ('signal 2') transduced through CD28 to priming and activation of naïve cells and amplification of cytokine gene expression and proliferative responses has provided a rationale for testing co-stimulatory blockade in patients. This has been achieved using a nondepleting humanized IgG1-CTLA4 fusion protein, which prevents CD80 and CD86 (B7 family members) from engaging CD28 (but also CTLA4) expressed on T cells. Initial studies confirmed that the agent was safe and well tolerated.⁵⁶ When administered as an intravenous infusion on days 1, 15 and 30, and then monthly thereafter, at a dose of 10 mg/kg combined with methotrexate, 60% of patients achieved ACR20 compared to 35.3% of controls; ACR50 responses were 36.5% versus 11.8%, respectively. CTLA4-Ig (licensed as Abatacept) has since been shown to inhibit radiographic progression and structural damage by ~50%, and is also effective in treating those patients who have had an inadequate response to TNF blockade as well as to methotrexate. From an immunological standpoint the data are interesting in several respects. First, the time to peak effect, which may take up to 1 year for some patients, is longer than for anti-TNF or anti-IL-6R therapy. This could reflect the presence of a significant number of co-stimulation-independent T cells (e.g., CD4⁺CD28^{null}) involved in disease progression, or perhaps the cumulative impact of blocking the activation and differentiation of naïve T-cell precursors over time. Second, inhibition of CD28 signals does not block the

development of regulatory T cells, as might have been predicted from mouse studies.

Anti-B-cell therapy

Rituximab is a humanized monoclonal antibody (IDEC-2B8) that recognizes human CD20, a 33–37 kDa membrane-associated phosphoprotein expressed on pre-B, immature and mature B cells but not plasma cells. Although CD20 ligation promotes B-cell activation, differentiation and cell cycle progression, its function is still poorly understood. The therapeutic effects of anti-CD20 are related to profound B-cell depletion due to antibody-dependent cell cytotoxicity, complement-mediated cell lysis, and/or triggering of intracellular pathways for apoptotic cell death.⁵⁷

The initial open-label studies in RA patients combined rituximab with cyclophosphamide and steroids, and so the precise contribution of rituximab to the clinical response was unclear. A pivotal placebo-controlled trial of rituximab therapy randomized 161 patients with rheumatoid factor-positive RA and compared the efficacy and safety of methotrexate alone (standard therapy) versus methotrexate plus rituximab (1000 mg on days 1 and 15), rituximab alone, or rituximab plus cyclophosphamide.⁵⁸ All groups received a 17-day course of steroids, which may facilitate B-cell depletion. Up to 43% of patients receiving combination of rituximab with methotrexate achieved a 50% improvement in clinical and laboratory parameters after 24 weeks (based on American College of Rheumatology response criteria – the ACR50), and this was at least as good as the rituximab/cyclophosphamide combination (41% achieving ACR50) and superior to methotrexate (13%) or rituximab alone (33%). The overall incidence of infection was similar across treatment groups, but seven serious infections were reported in rituximab-treated patients.

Detailed analysis of this and subsequent studies in RA patients indicate that the B-cell depletion, which may depend on *FCGR3* allelic variants, is profound (< 2%), with no major differences in infection rates between groups, with the possible exception of lower respiratory tract infections. Repopulation occurs at a mean of 8 months after treatment, comprises immature IgD⁺CD38⁺CD27⁺CD5⁺ B cells, and is associated with increased serum BLYS levels. Early relapse is associated with reconstitution of CD27⁺ memory B cells. The effects on serum immunoglobulin levels are modest, with levels remaining in the normal range. Selective and rapid decreases in pathogenic IgM, IgG and IgA rheumatoid factor (~ 60%) and IgG anti-CCP autoantibodies have been documented; these changes are more striking in rituximab responders. Antibody titers to tetanus toxoid or to pneumococcal capsular polysaccharides were only modestly affected (~ 25%). These changes are intriguing, given that terminally differentiated plasma cells do not express CD20. One possibility is that germinal center and marginal zone B cells may be resistant to anti-CD20. These encouraging results pave the way for testing alternative B cell-targeted therapies, of which anti-IL-6R should be included, but also LymphoStat-B (belimumab), TACI-Ig, and monoclonal antibody to BLYS/BAFF.

FUTURE PROSPECTS FOR THERAPY

There remain unmet needs in the treatment of RA. First among these must be the fact that for the majority of patients treatment is invariably lifelong, imposing a greater risk of toxicity and, as the immune system

degenerates, an increased risk of infection or lymphoproliferative disease. There is little doubt that early treatment with tight control offers the best outcome. From an immunological perspective, there remains a pressing need to develop immunological tools or immune biomarkers that can redefine disease subsets and measure effector and regulatory cell subsets using technology readily accessible to routine clinical laboratories. Although such tools may provide a better insight into disease pathogenesis, they can also be adapted to monitor the impact of therapeutic intervention, whether this turns out to be cell-based therapy or the application of novel immune modulators.

Juvenile idiopathic arthritis

Angelo Ravelli, Alberto Martini

53

The term juvenile idiopathic arthritis (JIA) includes all forms of arthritis which begin before the 16th birthday, persist for more than 6 weeks, and for which no cause is known.^{1,2} Therefore, there is no clinical or laboratory feature that is pathognomonic of JIA which represents an exclusion diagnosis that gathers together all forms of childhood chronic arthritis of unknown cause.

Over the years this heterogeneous material has been analyzed using different classification criteria in order to identify discrete clinical subsets that could correspond to different diseases. In the 1970s two classification systems were created: one in the USA (the juvenile rheumatoid arthritis (JRA) criteria) and one in Europe (the juvenile chronic arthritis (JCA) criteria). Although similar, these two classifications had a number of important differences that have prevented interchangeable use and comparative research. To try to overcome these problems, about 10 years ago, the International League of Associations for Rheumatology (ILAR) created a new classification system that could be transatlantically shared.³ This classification, in which the term JIA has been chosen instead of JRA or JCA, has the great merit of having unified classification criteria and terminology on the basis of current knowledge and represents a useful tool for international research. However, it still requires validation and consensus, has the limits inherent to any classification based on clinical criteria, and will probably be modified as new information on pathogenesis becomes available.⁴

For sake of simplicity, in the present chapter the term JIA will be used, even when studies performed using the JRA or JCA classification systems are quoted.

EPIDEMIOLOGY

Studies in American and northern European populations have reported an incidence and prevalence of JIA varying from 2 to 20 and from 16 to 150 per 100 000 respectively. Marked differences have been noted in the incidence of JIA subtypes according to geographical areas or ethnicity. In western countries the most common subtype is oligoarthritis; this subtype is rare in Costa Rica, India, New Zealand, and South Africa, where polyarthritis predominates.^{1,2}

JIA SUBTYPES

In order to be classified as JIA, arthritis must begin before the 16th birthday, persist for more than 6 weeks, and be of unknown origin. In the ILAR classification³ the various subtypes are identified by a definition and several exclusion items (Table 53.1) on the basis of the features presented in the first 6 months of disease.

SYSTEMIC ARTHRITIS

Systemic arthritis^{1,2} is quite distinct from the other JIA subtypes (Table 53.1). Although all subtypes share as a common feature the presence of arthritis and the risk of joint damage, systemic arthritis is also characterized by prominent systemic manifestations. The disease occurs as often in boys as in girls, does not show a preferential age at onset, and represents about 10% of all JIA cases. It can also occur in adults where it is known as 'adult-onset Still's disease.'

The hallmark is a high spiking daily fever greater than 39°C. Another characteristic feature is an evanescent, nonfixed, erythematous rash that typically occurs with fever peaks but may be produced by scratching (Koebner phenomenon); sometimes it can be urticaria-like and quite pruritic (Fig. 53.1). Hepatomegaly, splenomegaly, and generalized

KEY CONCEPTS

- >> Juvenile idiopathic arthritis (JIA) is not a single disease but includes a number of different conditions: some of these are not observed in adults whereas others are much more frequent in children than in adults or vice versa. Appropriate therapy and monitoring require a proper subtype diagnosis
- >> There are no laboratory or radiological features that are pathognomonic of JIA. The diagnosis is clinical and is based on meeting clinical criteria as well as excluding other diseases that cause chronic arthritis

Table 53.1 The International League of Associations for Rheumatology classification of juvenile idiopathic arthritis (JIA) (second revision)³

Systemic arthritis

Arthritis with, or preceded by, daily fever of at least 2 weeks' duration, that is documented to be quotidian for at least 3 days, and accompanied by one or more of the following:

1. Evanescent, nonfixed, erythematous rash
2. Generalized lymph node enlargement
3. Hepatomegaly and/or splenomegaly
4. Serositis

Exclusions: a, b, c, d (see below)

Oligoarthritis

Arthritis affecting 1–4 joints during the first 6 months of disease. Two subcategories are recognized:

1. Persistent oligoarthritis: affects no more than four joints throughout the disease course
2. Extended oligoarthritis: affects a total of more than four joints after the first 6 months of disease

Exclusions: a, b, c, d, e (see below)

Polyarthritis (rheumatoid factor-negative)

Arthritis affecting five or more joints during the first 6 months of disease: tests for rheumatoid factor are negative

Exclusions: a, b, c, d, e (see below)

Polyarthritis (rheumatoid factor-positive)

Arthritis affecting five or more joints during the first 6 months of disease: tests for rheumatoid factor are positive

Exclusions: a, b, c, e (see below)

Psoriatic arthritis

1. Arthritis and psoriasis *or*
2. Arthritis and at least two of the following:
 - a. Dactylitis
 - b. Nail pitting or onycholysis
 - c. Psoriasis in a first-degree relative

Exclusions: b, c, d, e (see below)

Enthesitis-related arthritis

1. Arthritis and enthesitis
2. Arthritis or enthesitis with at least two of the following:
 - a. Sacroiliac joint tenderness and/or inflammatory lumbosacral pain
 - b. Presence of human leukocyte antigen (HLA) B27
 - c. Onset of arthritis in a male after age 6 years
 - d. Ankylosing spondylitis, enthesitis-related arthritis, sacroiliitis with inflammatory bowel disease, Reiter's syndrome or acute anterior uveitis in a first-degree relative

Exclusions: a, d, e (see below)

Undifferentiated arthritis

Arthritis that does not fulfill inclusion criteria for any category, or is excluded by fulfilling criteria for more than one category

Exclusion criteria for the classification of JIA

- a. Psoriasis in the patient or a first-degree relative
- b. Arthritis in an HLA B27-positive male with arthritis onset after 6 years of age
- c. Ankylosing spondylitis, enthesitis-related arthritis, sacroiliitis with inflammatory bowel disease, Reiter's syndrome, acute anterior uveitis in a first-degree relative
- d. Presence of immunoglobulin M rheumatoid factor on at least two occasions more than 3 months apart
- e. Presence of systemic arthritis

Fig. 53.1 Rash associated with systemic arthritis. This evanescent, nonfixed, salmon-colored rash typically occurs with fever peaks; it may resemble urticaria and be quite pruritic.

lymph node enlargement are found in a sizable number of patients but are usually mild. Pericarditis or pleuritis occurs in a minority of patients and is more often mild and asymptomatic. Cardiorespiratory distress due to myocarditis or cardiac tamponade is very unusual.

Myalgias and abdominal pain may be intense during fever peaks. Arthritis is more often symmetrical and polyarticular. It may be absent at onset in about 30% of cases and develops during disease course.

Laboratory examinations show leukocytosis (with neutrophilia), very high erythrocyte sedimentation rate (ESR) values, and marked thrombocytosis. Anemia, sometimes profound, is common and microcytic. Different from the anemia of chronic disease observed in adult rheumatoid arthritis (RA), it appears mostly related to interleukin-6 (IL-6)-induced iron sequestration in the reticuloendothelial system.^{5,6}

About 5–8% of patients with systemic arthritis may develop a life-threatening complication called macrophage activation syndrome (MAS).^{1,2} MAS may follow an intercurrent viral illness or a change in medication. The syndrome includes a persistent (instead of spiking) high fever, pancytopenia, hepatosplenomegaly, liver insufficiency, coagulopathy with hemorrhagic manifestations, and neurologic symptoms. Laboratory features include elevated triglycerides and lactic dehydrogenase, low sodium levels, and markedly increased ferritin concentrations. The demonstration of active phagocytosis of hematopoietic cells by macrophage in the bone marrow is common. The syndrome is a life-threatening complication and has to be promptly recognized and treated.

OLIGOARTHRITIS

Oligoarthritis is defined on the presence of arthritis affecting one to four joints during the first 6 months of disease and the exclusion of other JIA subtypes which may present with arthritis in only a small number of joints (Table 53.1).

Although oligoarthritis as a whole is probably heterogeneous, by far the largest group of patients belongs to a quite well-defined form of

JIA.^{1,2} This form, which is not observed in adults, is characterized by an asymmetric arthritis, early onset (before 6 years of age), female predilection, high frequency of positive antinuclear antibodies (ANA), and high risk for developing chronic anterior uveitis. In support of the concept that these patients represent a homogeneous entity, a strong association with selected HLA alleles has been found (see section on genetic contribution, below). In Europe and the USA oligoarthritis represents about 50% of all forms of JIA whereas, as mentioned above, it is rare in other countries such as Costa Rica, India, New Zealand, and South Africa.^{1,2}

The knee is the most commonly affected joint, followed by the ankle. Other joints are affected less frequently. In about 30–50% of cases a single joint is involved at presentation. Joints are obviously swollen but in general not particularly painful, although joint contractures are frequent.

Acute-phase reactants are usually normal or moderately increased, although in some instances ESR may be quite high. ANA are detected in significant titers in about 70–80% of patients and represent a risk factor for the development of anterior uveitis.

The ILAR classification distinguishes two categories in the oligoarthritis subtype: *persistent oligoarthritis*, in which the disease remains confined to four joints or fewer and *extended oligoarthritis*, in which arthritis extends to more than four joints after the first 6 months of disease. In our opinion most of the patients classified as having either persistent or extended oligoarthritis belong to the same clinical entity.⁴ Indeed, the clinical characteristics of ANA-positive patients belonging to these two categories have been found to be homogeneous with respect to age at onset, sex ratio, asymmetry of articular involvement, and frequency of uveitis.⁷ This suggests that extended oligoarthritis is the same disease as persistent oligoarthritis but with a more severe outcome. The involvement of an upper limb and higher sedimentation rate at onset have been suggested as predictors for an evolution to the extended phenotype, which occurs in up to 50% of patients.⁸

Uveitis

A chronic, asymptomatic, nongranulomatous, anterior uveitis affecting the iris and the ciliary body (iridocyclitis) that can cause severe visual impairment is a characteristic feature of oligoarthritis and affects about 30% of patients.^{1,2} The onset is insidious and often entirely asymptomatic, in contrast with the painful acute uveitis that can be observed in enthesitis-related arthritis. One or both eyes may be involved. In fewer than 10% of patients uveitis is detected before the onset of arthritis and in about half of patients it occurs at the time of JIA diagnosis or shortly thereafter. Most children who develop uveitis do it within 5–7 years from the onset of arthritis. The course of uveitis may be relapsing or chronic and does not parallel the clinical course of arthritis. ANA-positive patients are at higher risk.

Uveitis can occur in other JIA subtypes such as rheumatoid factor (RF)-negative polyarthritis or psoriatic arthritis, especially if ANA-positive. As discussed later, there is evidence suggesting that ANA-positive patients represent a single disease entity, currently classified into different categories. Since uveitis is asymptomatic, children with JIA should be screened periodically by slit-lamp examination. Any patient with oligoarthritis or polyarthritis of early onset or, in general, with ANA-positive, RF-negative JIA should undergo slit-lamp examination at least every 3 months.

CLINICAL PEARLS

>> ***Uveitis in Juvenile idiopathic arthritis (Jia)***

>> Chronic anterior uveitis is a complication of JIA and can lead to blindness. It is mainly observed in oligoarthritis; antinuclear antibody positivity represents a risk factor. Since the onset is asymptomatic, patients at risk must undergo frequent ophthalmologic examinations. Early recognition and therapy are essential for prognosis

>> ***Macrophage activation syndrome***

>> Macrophage activation syndrome is a life-threatening complication of systemic arthritis and requires prompt recognition. It shares many similarities with the other forms of hemophagocytic lymphohistiocytosis

RHEUMATOID FACTOR-POSITIVE POLYARTHRITIS

RF-positive polyarthritis is defined as an arthritis that affects five or more joints during the first 6 months of disease in patients who test positive for immunoglobulin M (IgM) rheumatoid factor (Table 53.1). It represents a small minority (< 5%) of all cases of JIA. It is the same disease as adult RF-positive RA^{1, 2} and is usually observed in adolescent girls. Differences with respect to adults are related to the impact of the disease in a young person or in a child who is still growing.

RHEUMATOID FACTOR-NEGATIVE POLYARTHRITIS

RF-negative polyarthritis is defined as an arthritis that affects five or more joints during the first 6 months of disease in the absence of IgM RF (Table 53.1). It accounts for about 15–20% of all JIA cases and is the least defined and probably the most heterogeneous JIA subtype.^{1, 2} At least three distinct subsets can be identified from a clinical point of view.

Early-onset, ANA-positive polyarthritis

This form affects about one-third of patients and is characterized by the following common features: polyarthritis, asymmetric at the onset, affecting both large and small joints, and with onset before 6 years of age; ANA positivity; female predominance; and an elevated risk of developing chronic anterior uveitis. In this group of patients (see genetic contribution, below) a higher prevalence of human leukocyte antigen (HLA)-DRB1*0801 has been observed. All these features, including the HLA association, are identical to those observed in the majority of patients with oligoarthritis.⁴ This view has been supported by the demonstration that ANA-positive oligoarthritis shares homogeneous clinical features with ANA-positive RF-negative polyarthritis but not with ANA-negative RF-negative polyarthritis.⁷ The hypothesis that ANA-positive RF-negative polyarthritis and ANA-positive oligoarthritis are the same disease is also strongly supported by studies on the frequency of the various JIA subsets in different ethnic populations. Indeed, in those countries in which ANA-positive, early-onset, iridocyclitis-associated oligoarthritis is rare, ANA-positive, early-onset, iridocyclitis-associated RF-negative polyarthritis is also seldomly observed.⁴

Prolific symmetric synovitis

This is the more classic form of RF-negative polyarthritis.^{1, 2} Joint involvement is symmetric and affects large joints as well as the small joints of hands and feet. ESR is often elevated and ANA are usually negative. Age at onset is about 7–9 years. The relation between this form of arthritis and the RF-negative form that represent 25% of all forms of adult RA is unknown, since no reliable markers exist for both conditions.

Dry sinovitis

A subgroup of patients with polyarticular RF-negative arthritis show little palpable synovial thickening but gradually contract up in a manner which later leads to marked loss of function.^{1, 2} They tend to be about 7 or 8 years of age at presentation. There is usually little pain in the affected joints. The disease often follows a destructive course and is poorly responsive to common treatments. ESR in these patients is often normal or only modestly raised and ANA are negative. This type of RF-negative polyarthritis is uncommon; the peculiarities of its clinical picture suggest that it may include patients affected by some yet unknown genetic disease.

PSORIATIC ARTHRITIS

Psoriatic arthritis is defined by the presence of arthritis plus psoriasis or some psoriatic features (Table 53.1)^{1, 2} and represents about 5% of all cases of JIA, although estimates of its prevalence are very variable. It is our opinion that this subtype does not represent a clearly defined entity.⁴ Most patients who meet the ILAR criteria for psoriatic arthritis, in which patients with enthesitis are by definition excluded, have an early onset, an asymmetric oligoarthritis, are at risk for the development of iridocyclitis, and are frequently ANA-positive. All these characteristics are very similar to those observed in children with oligoarthritis. The main difference is that patients with psoriatic arthritis have a higher frequency of dactylitis and both small and large joints are involved. In previous studies on children with psoriasis and arthritis in which patients with enthesitis were not excluded, a proportion of patients presented with arthritis and enthesitis or developed sacroiliitis during follow-up, similarly to a sizable proportion of adult patients with psoriatic arthritis who share features with spondyloarthropathies.^{1, 2} So it appears that the association of psoriasis with arthritis does not define a unique entity.

ENTHESITIS-RELATED ARTHRITIS

This form of arthritis accounts for about 10% of JIA cases and mainly affects males after the age of 6 years.^{1, 2} It is characterized by the association of enthesitis and arthritis. Most patients are HLA-B27-positive. Enthesitis usually occurs around the foot and knees. The most common sites are the calcaneal insertions of the Achilles tendon or plantar fascia and the plantar fascia attachments to the metatarsal heads. Arthritis commonly affects the joints of the lower extremities. At variance with the other JIA subtypes, hip involvement is common at disease presentation. The disease is often remitting and may be mild. About half of patients have four joints or fewer affected during the entire course of the disease. A variable percentage progressively develop involvement of the axial skeleton.

Although characterized by increased extra-axial symptoms compared to adults, enthesitis-related arthritis belongs to the group of spondyloarthropathies. It can be viewed as an umbrella term that encompasses children with juvenile ankylosing spondylitis (who fulfill the criteria for adult ankylosing spondylitis) and with undifferentiated spondyloarthritides, including those with the formerly called seronegative enthesitis and arthritis syndrome.^{1, 2} ILAR criteria for the enthesitis-related arthritis category have been criticized because they do not consider psoriatic arthritis and reactive arthritis to be part of the juvenile spondyloarthritides and limit arthritis of inflammatory bowel disease to being only a descriptor of the disease.

UNDIFFERENTIATED ARTHRITIS

Undifferentiated arthritis does not represent a separate subset, but identifies patients who do not fulfill inclusion criteria for any category, or who are excluded by fulfilling criteria for more than one category.

ETIOLOGY AND PATHOGENESIS

The etiopathogenesis of JIA is still poorly understood. Moreover, the heterogeneity of JIA implies that multiple etiopathogenetic factors are involved.

As previously mentioned, RF-positive polyarticular JIA is considered the childhood equivalent of adult RF-positive RA. Enthesitis-associated arthritis, although characterized by increased extra-axial symptoms and modest sacroiliitis compared to adults, appears to belong pathogenetically to the spondyloarthropathies. Psoriatic arthritis is still a poorly defined condition in children and no reliable specific pathogenic studies have been performed in childhood.

GENETIC CONTRIBUTION

The attempt to define the genetic components of juvenile arthritis has been hampered by disease heterogeneity and classification problems. In addition, small numbers of patients have reduced the power of the studies. Despite these difficulties, it is clear that many diseases classified under the term JIA have a genetic component.⁹

Twin and affected siblings pairs studies

Data on disease concordance in identical twins are scanty. A Finnish study of JIA multicase families identified eight sets of monozygotic twins, two of whom were concordant for arthritis, giving a concordance rate of 25%. In the large US registry for JRA affected sibling pairs (ASPs), of 14 pairs of twins, 13 were concordant for disease onset (10 oligoarticular, 3 polyarticular).¹⁰

λ_s is calculated as the prevalence of the disease in siblings of affected individuals divided by the prevalence of the disease in the general population. Using the large US registry for JRA ASPs, the λ_s for juvenile arthritis has been estimated to be ~15; the HLA-DR accounted for ~17% of the risk for juvenile arthritis.^{9, 10} The most common onset type among 164 nontwin ASPs was oligoarticular (65% overall), supporting the concept that the shared genetic makeup between siblings plays a role in determining this onset type in particular.¹¹ The systemic-onset subtype did not show a high concordance rate and involved a small number of ASPs, suggesting a weak genetic component for this subtype.

HLA associations

Many associations between JIA subsets and HLA molecules have been described and some of these have been confirmed in several studies.^{1, 2, 9, 10}

Oligoarticular JIA has been consistently associated with HLA antigens. Positive associations include HLA-A2, HLA-DRB1*11 (a subtype of HLA-DR5), and HLA-DRB1*08. In contrast, HLA-DRB1*04 and HLA-DRB1*07 have been found to be significantly decreased. These associations are particularly significant in children with oligoarthritis and an early disease onset and have been confirmed with linkage analysis in ASPs.

RF-positive JIA is considered to be the childhood equivalent of adult RF-positive RA and, as in adults, is associated with HLA-DR4.

RF-negative polyarthritis is a heterogeneous condition and indeed HLA associations are not well defined. Interestingly, several groups have reported an increase in HLA-DR8, especially in RF-negative polyarticular patients with early age at onset, ANA positivity, and presence of iridocyclitis, supporting the view that this subset of polyarticular seronegative JIA and early-onset oligoarthritis are the same disease.⁴

Like adult spondyloarthritides, enthesitis-related arthritis has a strong association with HLA-B27. Systemic JIA (sJIA) has shown a poor association with HLA antigens.

Non-HLA associations

The non-HLA association in JIA have been less reproducible.^{10, 12} They included T-cell receptor variable genes, the proteasome LMP2 gene (LMP2BB), the transporters associated with antigen-processing genes (TAP1 and TAP2), the major histocompatibility complex (MHC) class I chain-related (MIC) A gene, neuroendocrine genes, the PTPN22 gene, osteopontin, and several cytokine genes (interferon (IFN)-regulatory factor 1, IL-1 α , TNF- α , IL-10, IL-6, and macrophage inhibitory factor (MIF)).

A single nucleotide polymorphism (SNP) (-174) in the regulatory region of the IL-6 gene that determines transcriptional response of the IL-6 gene to IL-1 and lipopolysaccharide has been associated with sJIA.¹³ A polymorphism in the 5' flanking region (-173) of MIF has been found to be associated with JIA.¹⁴ This polymorphism results in higher endogenous MIF production in the serum of healthy individuals and in higher MIF production in both the serum and synovial fluids of JIA cases. Moreover, in patients with sJIA, the carriage of this MIF polymorphism has been found to be correlated with worse long-term functional outcome.¹⁵ An SNP in the protein tyrosine phosphatase N22 (PTPN22) gene, an apparent negative regulator of T-lymphocyte activation, has been associated with various autoimmune diseases, including JIA.¹⁶ The results of the first genome-wide scan performed in 121 families containing 247 children with juvenile arthritis classified according to the JRA criteria have been published. The data support the hypothesis that multiple genes, including at least one in the HLA region, influence susceptibility to JRA, which is consistent with findings in other autoimmune diseases.¹⁷

ENVIRONMENTAL FACTORS

The hypothesis that an infection triggers the disease in genetically susceptible individuals, although attractive, remains unproven.^{1, 2} It is suggested by similarities with infection-induced arthritides such as Lyme arthritis, reactive arthritis, and parvovirus B19 and rubella virus-induced

arthritis. The early age at onset characteristic of oligoarthritis suggests that the disease may be secondary to an altered immunological response to common infectious agents that are encountered very early in life. It has also been suggested that the genetic association of oligoarticular JIA with HLA-DR alleles could be explained by mimicry with peptides from virus antigens such as Epstein–Barr virus.¹⁸

IMMUNE ABNORMALITIES

A large number of immunological abnormalities have been reported in JIA.^{1,2} Many are similar to those reported in adult RA and will be briefly summarized. Others are related to aspects that are more specific to JIA and will be described in more detail.

Autoantibodies

IgM RF is observed in RF polyarticular JIA, the childhood equivalent of adult RF-positive RA. Similarly, anti-cyclic citrullinated peptide antibodies are found in children with RF polyarticular JIA but not in other JIA subsets.^{1,2} Children with the other JIA subtypes can produce other types of RF, including “hidden RF” which are undetectable by traditional assays because they are bound to autologous IgG; however, the significance of these other antiglobulins is uncertain.

ANA, mainly associated with oligoarthritis, have been found to react against different chromatin constituents and against the DEK nuclear protein, a putative oncoprotein; however, none of these molecular targets is specific for oligoarticular JIA.¹

Synovitis

The inflammatory synovitis in JIA is similar to that observed in adult RA and does not appear to differ significantly among the different JIA subtypes.^{1,2} The synovium shows marked hyperplasia of the lining layer and an exuberant infiltration of the sub-lining layer with mononuclear cells, including T cells, B cells, macrophages, dendritic cells, and plasma cells. Aggregates of T and B cells can be observed in many patients either in the presence or absence of a germinal center reaction.^{19,20} The T-cell aggregates are composed predominantly of CD4 cells. The inflammatory T cells in the joints are highly Th-1 skewed, predominantly show an activated memory phenotype and express high levels of the chemokine receptors CCR5 and CXCR3.^{21,22} The hypertrophied synovial tissue is rich in microvessels. The pro-angiogenic factor vascular endothelial growth factor (VEGF) is highly expressed in synovial tissue; osteopontin correlates with new vascularization.^{1,2} The inflammatory process leads to pannus formation with cartilage and bone erosions mediated by degradative enzymes such as metalloproteinases.^{1,2}

Cytokines and calgranulins

Several studies have evaluated blood and synovial cytokine levels in children with the various JIA subtypes.^{1,2} However, with the exception of IL-6 in sJIA (see below), the results have often been quite inconsistent. These discrepancies may be due to differences in samples used (i.e., serum or plasma), sample handling, immunoassays, and patient classification criteria. TNF, IL-1, and IL-6 have been variably reported to be elevated in serum and synovial fluids of the various JIA subgroups.²³ As for adult RA, the observed potent therapeutic effect of anti-TNF agents in many

patients (see below) supports an important pathogenic role for this cytokine. Serum MIF levels have been shown to be increased in patients with JIA, with the highest levels observed in patients with systemic-onset JIA.²⁴ IL-18 has also been found to be increased in patients with sJIA.²⁵

The phagocyte-specific calcium-binding proteins known as calgranulins (S100A8, S100A9, and S100A12) have been detected in serum and synovial fluid of patients with JIA. Children with sJIA have serum concentrations of calgranulins up to 20-fold higher than those found in patients with other inflammatory disorders.²⁶

Type 2 cytokines

In a study investigating the pattern of expression of type 1 and type 2 cytokines in synovial tissues and fluids, IL-4 mRNA was identified significantly more often in patients with oligoarticular-onset disease than in those with polyarticular disease or adult RA. Similarly, IL-4 mRNA was detected more often in patients with a persistently pauciarticular disease course compared to those with a polyarticular course. Moreover, the combination of IL-4 and IL-10 mRNA was found more frequently in nonerosive compared with erosive disease, suggesting that IL-4, possibly in combination with IL-10, has an anti-inflammatory or disease-restricting role in JIA.²⁷

The expression of the chemokine receptor CCR4, associated with a Th2 response and selective accumulation of CCR4⁺ cells, has not been found in RA. A study has shown the presence in the synovial fluid of JIA patients of CD4⁺CCR4⁺ lymphocytes, which produced more IL-4 and less IFN- γ than CD4⁺CCR4⁻ cells. Increased numbers of CCR4⁺ cells were observed in samples collected early in the disease process.²⁸

Heat shock proteins

Heat shock proteins (hsp) are stress proteins that are increasingly produced when a cell is confronted with an environmental stress. In the adjuvant arthritis model, a T-cell clone specific for a mycobacterial hsp65 was found to induce disease by eliciting a cross-reactive response against cartilage proteoglycan.²⁹ Subsequently it was found that pre-immunization with mycobacterial hsp65 protects rats against subsequent induction not only of adjuvant arthritis but also of most of the other experimental models of arthritis. The subsequent analysis of T-cell epitopes of mycobacterial hsp65 showed that only conserved epitopes with a high degree of homology with the homologous rat peptide and capable of inducing T-cell responses to ‘self’ rat hsp60 can be protective, suggesting the induction of functional regulatory T cells.²⁹ Significant T-cell proliferative responses to human hsp60 have been found in patients with oligoarticular JIA early in disease; T-cell reactivity to human hsp60 seemed to be associated with disease remission.²⁹ Cells responsive to hsp60 express CD30 and produce IL-10.²⁹ More recently,³⁰ using computer algorithms for the identification of potential pan-DR-binding epitopes, the reactivity toward eight potential epitopes (from both self and microbial HSP60) binding to many HLA-DR have been studied in patients with oligoarticular and polyarticular JIA. Five of the eight peptides yielded proliferative T-cell responses in 50–70% of JIA patients irrespective of MHC genotype, but not in healthy or disease controls. Only peripheral blood mononuclear cells (PBMC) from patients with the disease produced IL-10, suggesting that in patients with oligoarticular disease the immune response to the identified HSP epitopes could contribute to disease remission.

Regulatory T cells

Regulatory T cells are T lymphocytes that suppress the activity of other T cells. Several different regulatory T-cell types have been described. There is now clear evidence that the population of naturally occurring regulatory T cells which constitutively express CD4 and CD25 plays an essential role in controlling autoimmunity. The development and function of regulatory T cells is critically dependent on the transcriptional repressor FoxP3.

In a recent study³¹ the CD4⁺CD25⁺ population in synovial fluid of JIA patients (mostly oligoarticular JIA) was shown to comprise both regulatory and effector T cells that could be distinguished by expression of CD27. CD4⁺CD25⁺CD27⁻ cells expressed low amounts of FoxP3, produced effector cytokines, and did not suppress T-cell proliferation. In contrast, CD4⁺CD25⁺CD27⁺ cells expressed a high amount of FoxP3, did not produce IL-2, IFN- γ , or TNF, and suppressed T-cell proliferation *in vitro*. These findings suggest that the combination of CD25 and CD27 allows identification of most regulatory T cells in inflamed tissues. These regulatory cells were, on a per-cell basis, fourfold more potent than the corresponding peripheral blood population, suggesting an activated state *in vivo*. The ratio of regulatory to activated T cells was found to be higher in patients with oligoarticular course than in those with polyarticular course. IL-7 and IL-15, present in synovial fluid of JIA patients, when added *in vitro*, were found to abrogate the suppressive activity of regulatory T cells, suggesting that in target tissues the function of regulatory T cells may be substantially limited by these cytokines.

Another study³² has found that patients with persistent oligoarticular JIA display a significantly higher frequency of CD4⁺CD25^{bright} T cells with concomitant higher levels of mRNA FoxP3 in the peripheral blood than extended oligoarticular patients. The frequency of CD4⁺CD25^{total} cells in synovial fluid was higher in patients with persistent than in those with extended oligoarticular JIA. Analysis of FoxP3 mRNA levels revealed a high expression in SF CD4⁺CD25^{bright} T cells of both patient groups and also a significant expression of FoxP3 mRNA in the CD4⁺CD25^{int} T-cell population. The CD4⁺CD25^{bright} T cells of both patient groups and the CD4⁺CD25^{int} T cells of persistent oligoarticular JIA were able to suppress responses of CD25^{negative} cells *in vitro*. SF CD4⁺CD25^{bright} cells showed an increased regulatory capacity *in vitro* compared to peripheral blood CD4⁺CD25^{bright} T cells.

IL-6 and IL-1

The cytokines critical to the pathogenesis of systemic JIA appear to be different from those in other JIA subtypes. Anti-TNF agents have indeed shown a rather limited effectiveness in systemic JIA as compared to other JIA subtypes.³³

Circulating levels of IL-6 are markedly elevated in patients with systemic JIA, increase during the peak of fever, and correlate with the extent and severity of joint involvement and with platelet counts.^{34,35} Both circulating and synovial fluid levels of IL-6 in systemic JIA are significantly higher than in polyarticular and oligoarticular JIA or in adult RA.³⁶ The overproduction of IL-6 could well explain many of the extra-articular manifestations of systemic JIA, including anemia^{5,6} and growth failure.³⁷ Together these findings led to the hypothesis that sJIA could be an IL-6-mediated disease.³⁶ Recently a study on 11 children with sJIA showed that treatment with a monoclonal antibody directed against the IL-6

receptor was associated with marked clinical improvement and normalization of the acute-phase reactants.³⁸

A subsequent paper³⁹ reported that the administration of the recombinant IL-1 receptor antagonist (IL-1Ra) to 9 patients with systemic JIA was also associated with a similar marked improvement and that serum from systemic JIA patients induces the transcription of innate immunity genes, including IL-1, in healthy peripheral blood mononuclear cells. These findings bear striking similarities to those observed in patients with autoinflammatory disorders due to a mutation in the NALP3/cryopyrin gene, in which IL- β is involved in disease pathogenesis and in which treatment with IL-Ra resolves the clinical symptoms and normalizes acute-phase reactants. Of note, these diseases are characterized as systemic JIA by elevated serum IL-6 levels that normalize rapidly during IL-1Ra therapy. These observations raise the possibility that at least some forms of systemic JIA could represent autoinflammatory diseases.

Macrophage activation syndrome

As previously mentioned, for unknown reasons MAS occurs much more frequently in systemic arthritis than in other rheumatic diseases. MAS is characterized by a highly stimulated but ineffective immune response and is very similar to the other forms of hemophagocytic lymphohistiocytosis (HLH), the best known of which is familial HLH (FHLH).⁴⁰ Several independent genetic loci related to the release of cytolytic granules from natural killer (NK) and CD8 T lymphocytes have been associated with FHLH: perforin mutations have been observed in about 40% of patients. These mutations cause a severe impairment of cytotoxic function which, through mechanisms that have not yet been well elucidated, leads to an excessive expansion and activation of cytotoxic cells with hypersecretion of proinflammatory cytokines. These cytokines are produced by activated T cells and histiocytes that infiltrate all tissues and lead to tissue necrosis and organ failure. In perforin-deficient mice, the animal model of FHLH, although the serum levels of multiple cytokines, including IL-6, IL-18, and IFN- γ , are increased, only antibody to IFN- γ prolongs survival.

The mechanisms leading to cytolytic defects in immune-competent patients with acquired HLH are less clear.⁴⁰ Patients with virus-associated HLH also have very low or absent cytolytic NK cell activity. However, in contrast to FHLH, this phenomenon appears to be related to profoundly decreased number of NK cells rather than to impaired perforin expression. Notably, NK function has been found to recover completely in some patients after the resolution of the acute phase.⁴⁰

Depressed NK activity, with or without abnormal perforin expression, may also be involved in the pathogenesis of MAS associated with systemic JIA.⁴⁰ NK activity was investigated in 7 patients with systemic arthritis and MAS during the acute stage or after resolution. In some patients, decreased NK activity was associated with very low numbers of NK cells but mildly increased levels of perforin expression in NK cells and cytotoxic CD8 T lymphocytes, a pattern somewhat similar to that in virus-associated HLH. In other patients, very low NK activity was associated with only mildly decreased numbers of NK cells but very low levels of perforin expression in all cytotoxic cell types, a pattern indistinguishable from that seen in FHLH. Remarkably, most of the patients with low perforin expression had a history of multiple episodes of MAS.⁴⁰ Hepatic biopsies in patients with various types of HLH, including MAS, revealed extensive infiltration of the liver by IFN- γ -producing CD8 T lymphocytes and hemophagocytic macrophages

KEY CONCEPTS

PATHOGENESIS OF JUVENILE IDIOPATHIC ARTHRITIS (JIA)

- >> The various JIA subtypes presumably correspond to different multifactorial diseases and likely represent complex genetic traits
- >> The pathogenic features of systemic arthritis appear to be different from those of the other JIA subtypes and share similarities with those of autoinflammatory disorders

secreting TNF- γ and IL-6.⁴¹ It has been suggested that hyperproduction of IL-18 (which strongly induces Th-1 responses and IFN- γ production and enhances NK cell cytotoxicity) and an imbalance between levels of biologically active free IL-18 and those of its natural inhibitor (the IL-18-binding protein) may also play a role in secondary hemophagocytic syndromes, including MAS.⁴² In a child with systemic JIA and MAS, the bone marrow was identified as the origin of the increased serum IL-18.⁴³

COURSE AND PROGNOSIS

JIA is not a benign condition; a sizable proportion of patients develop articular damage and enter adult life with still-active disease.^{1,2} It would therefore be of great importance to predict early in the disease course the ultimate outcome in order to tailor treatment to the risk of disability. However, although most children can be categorized in one of the various JIA subsets after the first 6 months of disease, this does not allow a reliable prediction of the potential outcome since evolution can differ greatly among patients belonging to the same onset type.

SYSTEMIC ARTHRITIS

Systemic arthritis has a variable course.^{1,2} In about half of patients the disease is characterized by a monocyclic or an intermittent course with relapses followed by intervals of remission; in these cases the arthritis accompanies the episodes of fever but remits when systemic features are controlled. The long-term prognosis of these patients is usually good. In the other half of patients the disease follows an unremitting course. In many cases systemic symptoms eventually resolve, leaving chronic arthritis as the major long-term problem. This second group of patients with an unremitting disease course is probably the most severe among all JIA subtypes and can lead to severe joint destruction. Death was once principally related to the development of amyloidosis, that now appears to be a very uncommon complication. Nowadays, MAS remains the most serious and potentially fatal threat and has to be promptly recognized and treated.

OLIGOARTHRITIS

In general patients with oligoarthritis have the best outcome. Moreover, their prognosis has greatly improved in the last decades thanks to the widespread use of intra-articular steroids for the prevention of deformities

Fig. 53.2 Posterior synechiae, a complication of chronic anterior uveitis associated with juvenile idiopathic arthritis. The irregularities of the margins of the pupil are due to fibrous adhesions between the iris and the lens capsule.

secondary to joint contractures. Nevertheless, some series have reported rates of remission after 6–10 years of disease of only 23–47%.^{1,2} The percentage of patients who develop extended oligoarthritis has been reported to vary between 20 and 50%.^{9, 59} As may be expected, joint erosions occur more frequently in patients with a polyarticular course.⁸

The outcome of uveitis depends very much on early diagnosis and treatment. Prior to careful monitoring for uveitis with periodic slit-lamp examinations, a severe outcome was observed in more than one-third of patients. Now only a minority of patients suffer complications which can however be significant and include posterior synechiae (between the iris and the lens), cataract, and band keratopathy (Fig. 53.2). A small minority of patient may experience progressive disease leading to blindness despite adequate monitoring and treatment.¹

OTHER SUBTYPES

RF-positive polyarthritis has the same poor long-term outcome as RF-positive adult RA. RF-negative polyarthritis has a variable outcome, reflecting the heterogeneity of the subtype. The prognosis of psoriatic arthritis as defined by the current ILAR criteria is not yet defined. In general, patients have a poorer outlook compared with those with oligoarthritis, with more frequent involvement of small joints and an increase in the number of affected joints. A variable percentage of patients with enthesitis-related arthritis progressively develops involvement of the joints of the axial skeleton.

GROWTH ANOMALIES

A characteristic feature of chronic arthritis in children is the effect it may have on bone and joint development.^{1,2} Local growth disturbances occur at sites of inflammation resulting in either overgrowth or undergrowth of

Fig. 53.3 Leg-length inequality secondary to asymmetric knee involvement. The overgrowth of the juxta-articular bone extremities is due to accelerated development of ossification centers, possibly related to inflammation-induced increased vascularization and growth factor release.

the juxta-articular bone extremities. Overgrowth is due to accelerated development of ossification centers, possibly related to inflammation-induced increased vascularization and growth factor release. Asymmetric knee involvement often results in lengthening of the affected leg with leg-length inequality (Fig. 53.3). Many inequalities resolve with growth if arthritis is controlled.

Undergrowth is secondary to growth center damage or premature fusion of epiphyseal plates. When extremities are involved, it may be symmetric, resulting in small hands or feet, or it may be isolated with selective brachydactyly. Arthritis of the wrist may cause growth failure of the ulnar head with shortened ulna and ulnar deviation of the carpus. Unilateral involvement of the temporomandibular joint may result in

mandibular asymmetry, and bilateral involvement may cause marked micrognathia. Similarly, involvement of the cervical spine, which is frequent in patients with JIA, may cause undergrowth of the vertebral bodies, resulting ultimately in a short neck. Anomalies in growth and morphogenesis of skeletal segments also result from anomalous tractions, on growing structures, secondary to muscular spasm and periarticular fibrosis. They are more marked in children with precocious onset of arthritis and very active disease. A characteristic developmental anomaly of the hip is often observed in children with early onset of arthritis. It includes enlargement and flattening of the femoral head, incompletely covered by an underdeveloped acetabulum, and a short, squat, valgus and anteverted femoral neck.

General growth abnormalities may be secondary to treatment with glucocorticoids as well as to the inflammatory process, particularly in patients with severe, persistently active, systemic JIA.

In affected joints periarticular osteoporosis is common. The use of corticosteroids may lead to generalized osteoporosis.

DIFFERENTIAL DIAGNOSIS

Since JIA is an exclusion diagnosis, by definition any other cause of chronic arthritis has to be ruled out. With the exception of enthesitis-related arthritis in which joint involvement can be quite painful or transient and recurrent, the arthritis of JIA is characterized by persistent joint swelling which is often not particularly painful, especially in the oligoarticular subtype. As in other inflammatory arthritides, joint stiffness is very common.

A wide range of different conditions can cause swelling and limitation of motion in a joint. These include other inflammatory or autoimmune diseases, infectious and post-infectious conditions, hematologic and neoplastic disorders, metabolic diseases, and congenital or acquired disorders of bones. The differential diagnosis is therefore very vast and beyond the scope of this chapter.

The condition that is essential to exclude immediately is septic arthritis, which is usually monoarticular and characterized by extreme joint tenderness and refusal to move the joint. The next most critical conditions to be excluded are neoplastic diseases and in particular leukemia and neuroblastoma. They are often characterized by severe bone pain which may have periods of exacerbation and remission: the pain is out of proportion to physical findings.

Monoarticular swelling can be caused by various conditions, including septic arthritis, hemophilia, osteochondritis dissecans, synovial hemangioma, and tuberculosis. Tuberculosis is characterized by an indolent course that can mimic JIA; therefore a purified protein derivative test has to be performed in any child with monoarthritis, especially of the knee. Hip involvement is very uncommon in JIA at presentation, with the exception of enthesitis-related arthritis. Lyme disease can cause mono- as well as oligoarthritis and has to be considered especially in endemic areas. Gouty arthritis as well as other crystal-induced arthropathies is extremely rare in children and is usually associated with a genetic disease. Chronic uveitis associated with rash and an oligoarthritis with marked periarticular involvement is characteristic of Blau syndrome.

Inflammatory bowel diseases can mimic JIA at presentation. Other inflammatory or autoimmune diseases such as systemic lupus erythematosus, rheumatic fever, Henoch-Schönlein purpura, Kawasaki disease, or other vasculitides can usually be differentiated from JIA on both articular

THERAPEUTIC PRINCIPLES

- >> Children are not small adults and juvenile idiopathic arthritis (JIA) is different from adult rheumatoid arthritis. Therefore, the evaluation of the safety and efficacy of any new drug in JIA needs appropriately designed controlled trials
- >> Treatment approaches differ among the various JIA subtypes
- >> Growth and developmental abnormalities can be unique complications in young patients

and extra-articular features. Progressive joint contractures are observed in metabolic diseases such as mucopolysaccharidosis and mucopolipidosis.

Bacterial infections and malignancy as well as other causes of persistent fever must be ruled out before considering the diagnosis of systemic arthritis. MAS requires a prompt diagnosis and must not be confused with septic shock or other causes of hemophagocytic lymphohistiocytosis.

TREATMENT

Although we still do not possess drugs that are able to 'cure' the disease, the prognosis of JIA has greatly improved, with respect to even a decade ago, thanks to substantial progresses in disease management. Since JIA is not a single disease, treatment approach also varies among JIA subtypes. Since the course (even within each subtype) is difficult to predict, it is impossible at onset to tell what medications will be needed to control the disease. The goal of treatment is to gain complete control of the disease, to preserve the physical and psychological integrity of the child, and to prevent any long-term consequence related to disease or therapy. Periodic X-ray examination of the affected joints is needed to document progression of erosive disease.⁴⁴

Optimal management of JIA requires a multidisciplinary approach that involves pediatric rheumatologists, nurses, physical and occupational therapists, social workers and, when indicated, psychologists, orthopedic surgeons, and ophthalmologists.

MEDICAL TREATMENT

Oligoarthritis and polyarthritis

Nonsteroidal anti-inflammatory drugs (NSAIDs) have been the mainstay of JIA treatment for decades.^{1,2} Their role remains important and most children with JIA are started on an NSAID. Just a few NSAIDs are approved for use in children; the most commonly used include naproxen, ibuprofen, and indometacin. They are usually quite well tolerated and side effects are less common than in adults. Acetylsalicylic acid is much less used than in the past because of the less favorable safety profile. Experience with cyclooxygenase-2 inhibitors in children is very limited.

Intra-articular steroid injections with triamcinolone hexacetonide are frequently needed at disease onset or during disease course. In mono- or oligoarticular arthritis they are often used and may be indicated in association of or in substitution for NSAIDs. They are rapidly effective and, most importantly, they break the vicious circle that leads to deformities

(such as valgus knee) secondary to contractures. Although they are not curative, their effect may last for long periods.

In those children in whom the disease is not well controlled by NSAIDs and steroid injections, a second-line agent is often needed. These patients usually have arthritis with a polyarticular onset or course. There is general consensus that in these patients second-line therapy should be introduced quite early in the disease course in order to try to prevent disease progression. The second-line agent of first choice in JIA is methotrexate (MTX). A controlled study has shown its efficacy at a dose of 10 mg/m² per week.⁴⁵ A further study has shown that the plateau of efficacy is reached at 15 mg/m² per week and that higher doses are not accompanied by a better effect.⁴⁶ MTX is usually well tolerated, especially if associated with the administration of folic or folinic acid. At doses >10 mg/m² per week, parenteral administration is advisable. Improvement is usually apparent in 6–12 weeks.⁴⁷

In those patients who have an unsatisfactory response to MTX and in whom the disease remains active, treatment with anti-TNF agents is indicated. A controlled study has shown the efficacy of etanercept, at a dose of 0.4 mg/kg subcutaneously twice a week in patients with JIA who were resistant or intolerant to MTX.⁴⁸ Subsequently, other studies have confirmed the remarkable and rapid efficacy and the good safety profile of the drug in JIA. Since cases of reactivated tuberculosis have been reported during treatment with TNF inhibitors, all children should have a documented negative tuberculosis test before starting therapy.^{1,2} Etanercept is at present the only anti-TNF agent registered for pediatric use. However, controlled trials with other anti-TNF agents such as infliximab and adalimumab have recently been performed and the results will soon be published. To underline the need for controlled studies specifically performed in children, the infliximab study has shown that, although both the dosages of 3 and 6 mg/kg were effective, children treated with 3 mg/kg developed a much higher percentage of antibodies against infliximab and experienced a higher rate of infusion reactions.⁴⁹ Anti-TNF agents have also been reported to be effective in juvenile spondyloarthritis.⁵⁰

As for the other second-line agents, seminal studies performed many years ago have shown that hydroxychloroquine and D-penicillamine are not more effective than placebo in RF-negative JIA.¹ Sulfasalazine^{1,2} may be considered as the second-line agent, especially in enthesitis-related arthritis, although there are no data showing that it is better than MTX for this indication; it has to be avoided in systemic arthritis for the increased risk of toxicity. A recent trial has shown the efficacy of leflunomide in JIA⁵¹ but experience with this drug is still limited.

Systemic steroids (prednisone) are used only as a bridge drug when the disease is very active and time is required before second-line agents (such as MTX) can show their efficacy.

RF-positive polyarthritis is the equivalent of adult RF-positive RA and the therapeutic approach is the same.

Systemic arthritis

Systemic arthritis frequently does not respond to NSAIDs alone. In this case, when the diagnosis is firmly established, prednisone therapy is often indicated. Once disease control is reached, steroid therapy has to be progressively tapered. Indeed, the use of steroids should be limited as much as possible because of their severe side effects which, in children, also include growth retardation. Vitamin D and calcium supplements to try

to prevent osteoporosis as well as dietary counseling are indicated. Treatment of MAS relies on prompt recognition of this complication and the use of high-dose steroids and Cyclosporine.^{1,2} In children characterized by a polycyclic course, steroids and NSAIDs may be sufficient to control episodes of disease activity. In unremitting disease, steroid tapering is often accompanied by recurrence of systemic symptoms and arthritis. Although systemic symptoms often, but not always, fade during disease course, arthritis persists and often represent the main determinant for disease outcome. MTX is probably less effective in systemic arthritis than in other JIA subtypes.^{1,2} Etanercept is also less effective in systemic arthritis than in other JIA subtypes.³³ The use of thalidomide has been proposed for resistant systemic arthritis.⁵² In patients with very severe unremitting disease autologous bone marrow transplantation has been performed.⁵³ In the rare cases that develop amyloidosis, alkylating agents are indicated.^{1,2}

As mentioned above, IL-6 has been suggested to play a major role in the pathogenesis of systemic JIA and an uncontrolled trial using a monoclonal antibody against the IL-6 receptor has shown very promising results in 11 patients with systemic JIA.³⁸ Moreover, recently treatment with IL-1Ra has also been associated with marked clinical improvement in 9 patients with systemic JIA.³⁹ The efficacy of these potentially very useful treatments requires confirmation in controlled clinical trials. In our experience (manuscript in preparation) some patients with systemic arthritis respond very well to IL-1Ra, others have only a partial response, while others are resistant. It is therefore conceivable that treatment with these two cytokine inhibitors could represent not only a very important therapeutic advance but could also help in unraveling the clinical heterogeneity of systemic arthritis.

Uveitis

Early diagnosis is very important for the success of therapy, which has to be managed by an ophthalmologist.^{1,2} The initial approach consists of glucocorticoid eye drops with mydriatics to dilate the pupil and prevent the occurrence of posterior synechiae. Concurrent therapy with NSAIDs is often used. In patients with disease resistant to topical therapy systemic steroid administration and/or subtenon injection of corticosteroids are required. In disease not controlled by the above measures several drugs have been claimed to be effective, including MTX, Cyclosporine, and alkylating agents. However no controlled trials exist. The efficacy of etanercept is controversial while infliximab has been anecdotally reported to be of benefit.

OTHER THERAPEUTIC ASPECTS

Physiotherapy and occupational therapy are important components of the therapeutic approach to any patients with JIA. In general, children limit their activities by themselves and should not be restricted. Swimming and bicycle riding, which do not put significant weight on the joints, should be encouraged. An orthodontic approach is often indicated in case of temporomandibular joint involvement.

Arthroscopic synovectomy may be indicated in a few cases to debulk proliferative synovitis resistant to other treatments. Soft-tissue release may be useful in selected cases but the intervention as well as the following postoperative rehabilitation have to be performed by experienced personnel.

Total arthroplasty, in particular of the hip and knee, represents a successful option in the presence of severe functional impairment and is generally delayed until growth has stopped. It presents special problems and has to be performed by orthopedic surgeons with specific experience.

JIA has a great psychological impact on the child and family. Children should be encouraged to attend school normally as well as take part in all the activities that are appropriate for their age. Parents may tend to protect the child excessively and limit activities; this can affect the proper development of the child's personality and prevent him or her from acquiring adequate self-confidence and self-esteem. When indicated, psychological support can be required. A website with information for families of children with rheumatic diseases is available in 50 languages.⁵⁴

Sjögren's syndrome

Stanley R. Pillemer

54

Sjögren's syndrome (SS) is a debilitating systemic autoimmune disorder in which inflammation of the epithelial tissues, including exocrine glands, is prominent.¹ Salivary and lacrimal gland involvement is very common and associated with decreased production of saliva and tears. Other epithelial components of the body are commonly involved, including the skin, as well as the urogenital, respiratory, and gastrointestinal tracts. In addition, other systemic autoimmune manifestations occur, including synovitis, neuropathy, vasculitis, elevated immunoglobulin levels and autoantibodies, particularly antinuclear antibodies, anti-SSA, anti-SSB, and rheumatoid factor. SS may be associated with malignancies, especially non-Hodgkin's lymphoma.²

■ EPIDEMIOLOGY ■

Reported prevalences of primary SS vary from 0.05% to 4.8% of the population,^{3,4} and SS appears to increase in frequency with age.³ Likely, the prevalence of primary SS is on the order of 0.3–0.6%.⁴ The incidence of new cases of primary SS is estimated at ~4 per 100 000 population per year.³ The diagnosis is most frequently made in mid-life, but can occur at any age. The onset is most often insidious, and diagnosis may be delayed for a number of years.⁵ The female-to-male ratio is about 9:1.

Mortality rates in SS may be increased, perhaps more so for secondary SS than primary SS.⁶ Approximately 5% of patients with primary SS develop B-cell lymphomas, which may contribute to excess mortality.² However, it is not yet clear whether the overall mortality from all causes for primary SS is increased when compared with the general population.⁶ Differences in classification criteria may complicate the interpretation of epidemiological data.

■ CLASSIFICATION CRITERIA AND DIAGNOSIS ■

Published classification criteria for SS have included the requirement of keratoconjunctivitis sicca (KCS), xerostomia (XS), and autoantibodies. Preliminary European criteria were revised by the American–European Consensus Group because it was possible for individuals without

evidence of autoimmunity (negative labial salivary gland biopsy and negative serology) to meet them.⁷ Those criteria, shown in Table 54.1, are currently the most widely used. Rules for applying the criteria and the exclusions for SS are shown in Table 54.2. Patients meeting these current classification criteria may be considered for practical purposes to have a diagnosis of SS. The differential diagnosis for SS includes the disorders listed as exclusions.

SS may be categorized into primary and secondary forms.⁸ If SS coexists with other autoimmune diseases, such as rheumatoid arthritis, systemic lupus erythematosus (SLE), scleroderma, polymyositis, and polyarteritis nodosa, it is referred to as secondary SS.⁸ Otherwise it is called primary SS. However, this terminology is misleading. For example, as sometimes occurs, a patient with primary SS may subsequently develop SLE. The patient is then said to have secondary SS. There is no evidence that the SS is secondary to SLE in such cases. Such a case could equally be regarded as a case of primary SS with secondary SLE.

■ PATHOGENESIS ■

Although the cause of SS remains unknown, a considerable body of research spanning decades has elucidated many features of the immunopathogenesis of the disorder.^{5, 9, 10} Damage to epithelial cells by unknown environmental agents, such as viruses or toxins, might initiate a cascade of events in genetically prone hosts, resulting in the development of SS. A number of viruses have a tropism for salivary glands.¹¹ Viruses implicated in SS include herpes viruses, such as Epstein–Barr virus, cytomegalovirus, as well as human herpes virus (HHV)-6 and HHV-8; and retroviruses, such as human T-cell lymphotropic virus-1, human retrovirus 5 and human immunodeficiency virus (HIV)-1. However, the salivary involvement in HIV infection affects a higher proportion of males and is associated with CD8 T cells, rather than the increase in CD4 cells occurring in SS, and autoantibodies are less frequent. Hepatitis C virus can also result in salivary gland swelling and may masquerade as SS. Enteroviruses, such as coxsackievirus, have been recently implicated in SS. Coxsackie viral RNA and enteroviral capsid protein VP1 were found in minor salivary gland epithelial cells and lymphocytic infiltrates from SS patients, but not controls.¹² However, of the

Table 54.1 Revised classification criteria for Sjögren's syndrome

I. Ocular symptoms: a positive response to at least one of the following questions:

Have you had daily, persistent, troublesome dry eyes for more than 3 months?

Do you have a recurrent sensation of sand or gravel in the eyes?

Do you use tear substitutes more than three times a day?

II. Oral symptoms: a positive response to at least one of the following questions:

Have you had a daily feeling of dry mouth for more than 3 months?

Have you had recurrently or persistently swollen salivary glands as an adult?

Do you frequently drink liquids to aid in swallowing dry food?

III. Ocular signs, i.e., objective evidence of ocular involvement defined as a positive result for at least one of the following two tests:

Schirmer's I test, performed without anesthesia (≤ 5 mm in 5 minutes)

Rose Bengal score or other ocular dye score (≥ 4 according to van Bijsterveld's scoring system).

IV. Histopathology: in minor salivary glands (obtained through normal-appearing mucosa) focal lymphocytic sialoadenitis, evaluated by an expert histopathologist, with a focus score ≥ 1 , defined as a number of lymphocytic foci which are adjacent to normal-appearing mucous acini and contain more than 50 lymphocytes per 4 mm² of glandular tissue.

V. Salivary gland involvement: objective evidence of salivary gland involvement defined by a positive result for at least one of the following diagnostic tests:

1. Unstimulated whole salivary flow (≤ 1.5 ml in 15 minutes)

2. Parotid sialography showing the presence of diffuse sialectasias (punctate, cavitory, or destructive pattern), without evidence of obstruction in the major ducts

3. Salivary scintigraphy showing delayed uptake, reduced concentration, and/or delayed excretion of tracer

VI. Autoantibodies: presence in the serum of the following autoantibodies:

Antibodies to Ro(SSA) or La(SSB) antigens, or both

viral infections implicated in SS in the past, no specific organism has emerged as the cause of SS.¹¹ Bacteria, such as *Helicobacter pylori* have been considered as potential agents involved in the pathogenesis of SS. However, this organism appears to be no more common in SS patients than healthy controls and not all patients carry *H. pylori*.¹³

Sex and other genetically determined factors have a role in host susceptibility to SS.⁹ SS and other autoimmune diseases, such as SLE, are more common in females than males. Females show greater humoral and cellular immune responses than males. Hormonal factors, such as a relative lack of androgens, may have a pathogenic role in SS.¹⁴ In addition, pregnancy is associated with modulation of autoimmune diseases. The severity of a number of autoimmune diseases change during pregnancy and postpartum,

Table 54.2 Revised rules for classification

For primary SS

In patients without any potentially associated disease, primary SS can be defined as follows:

1. The presence of *any four out of the six items* is indicative of primary SS, as long as either item IV (histopathology) or VI (serology) is positive

2. The presence of *any three of the four objective criteria items* (i.e., items III, IV, V, VI)

3. *The classification tree procedure* represents a valid alternative method for classification, although it should be more properly used in clinical-epidemiological surveys (Fig. 54.2)

For secondary SS

In patients with a potentially associated disease (for instance, another well-defined connective tissue disease), the presence of *item I or item II plus any two from among items III, IV, and V* may be considered as indicative of secondary SS

Exclusion criteria: past history of head and neck radiation therapy, hepatitis C infection, acquired immunodeficiency disease (AIDS), pre-existing lymphoma, sarcoidosis, graft-versus-host disease, use of anti-cholinergic drugs (within four half-lives of the drug).

suggesting a role for hormonal fluctuations. Besides the possible role of sex hormones, hypofunction of the hypothalamic-adrenal-pituitary adrenal (HPA) axis occurs in SS and other autoimmune rheumatic diseases.¹⁴ Such HPA axis abnormalities can be congenital or acquired.

Genetic factors other than those above may contribute toward the development of SS.⁹ Family members may have an increased prevalence of SS and autoantibodies, mostly anti-Ro/SSA. The HLA-DR3 and HLA-DQ2 alleles are more common in white patients with primary SS. Different alleles predominate in African-Americans and Japanese patients.¹⁵ Identical twins appear to have phenotypically similar disease, including the fine specificities of anti-Ro.⁹ In some patients, the transporters associated with antigen processing (TAP) gene alleles, TAP1 (0101) and TAP2 (0101), and microsatellite a2 alleles may be more frequent.¹⁵

Whether the disease is congenital or acquired, patients with SS appear to have a greater tendency toward apoptosis of the epithelial cells in the salivary glands.¹ An overview of the pathogenesis of SS is shown in **key concepts**. Apoptotic epithelial cells release material including RNA and RNA-binding proteins, such as Ro/SSA and La/SSB, allowing for the development of autoantibodies directed against Ro/SSA and La/SSB.¹⁰ Immune complexes containing Ro/SSA-anti-Ro/SSA occur in SS, and can bind to Fc receptors on plasmacytoid dendritic cells, become internalized, and activate Toll-like receptors (TLRs).¹⁰ The activation of TLRs results in a cascade of events that increases the production of type I interferons (IFN), such as IFN- α .¹⁰ This is consistent with the type 1 IFN signature seen in salivary gland tissue in SS and represented by increased expression of type 1 IFN response genes. The upregulation of type I IFN response genes can increase expression of IFN- γ and B-lymphocyte stimulator (BLyS; also known as BAFF). BLyS promotes the survival and proliferation of B cells. Expansion of B cells capable of undergoing random mutations may partly account for the relatively high frequency of B-cell lymphomas in SS.

KEY CONCEPTS

PATHOGENESIS OF SJÖGREN'S SYNDROME

- >> Sjögren's syndrome is a systemic autoimmune disease that shows characteristic tissue inflammation, which occurs in lacrimal and salivary glands, as well as other exocrine and epithelial tissues; autoantibodies, such as anti-SS-A and anti-SS-B; and increased expression of type 1 interferon response genes
- >> Environmental agents and genetic factors likely result in apoptosis of epithelial cells that release RNA, RNA-binding proteins, such as SS-A and SS-B, and other debris
- >> Autoantibodies directed against SS-A (60 and 52-kDa proteins) and SS-B (48-kDa proteins) result in SS-A/anti-SS-A and SS-B/anti-SS-B immune complexes
- >> Immune complexes can bind to Fc receptors on plasmacytoid dendritic cells in the target tissues. Internalization of immune complexes may occur, resulting in the activation of Toll-like receptors (TLRs), which may result in the increased production of type I interferons, such as interferon- α
- >> Interferon- α induces T cells in tissue infiltrates to produce BlyS/BAFF that facilitates the survival and proliferation of B cells. These effects may relate to the increase risk of B-cell lymphomas in Sjögren's syndrome
- >> Although B cells have an important role in Sjögren's syndrome, the predominant infiltrating cells in the glands and mucosa-associated lymphoid tissues (MALT) in which lymphomas may arise are CD4 T cells that release Th1-type cytokines.

The distinctive features of SS include focal periductal mononuclear cell infiltration in exocrine tissues.¹ The exocrine infiltrate contains mostly T cells and, to a lesser extent, B cells, macrophages, and mast cells.^{1,10} The majority of the T cells are CD4 helper cells of the CD45RO memory cell phenotype. These cells express the α/β T-cell receptor and activated lymphocyte function-associated antigen type 1 (LFA-1), and may have a role in promoting B-cell hyperactivity. Adhesion molecules and LFA-1 facilitate homing in exocrine tissue, which at times results in the formation of follicular structures similar to those seen in lymph nodes. Despite increased expression of Fas, the infiltrating periductal lymphocytes appear to be resistant to apoptosis, favoring persistence of autoreactive cells in the exocrine tissues. Apoptosis may be suppressed by the proto-oncogene Bcl-2.¹

In SS, both salivary and lacrimal gland epithelial cells express HLA-DR molecules. This enables these epithelial cells to present exogenous antigens and autoantigens to CD4 T cells,¹ promoting the production of cytokines and the stimulation of B-cell proliferation and differentiation. In addition, B-cell activation is typical in SS and may evolve into B-cell lymphoid malignancy.¹ Proinflammatory cytokines, IL-1 β , IL-6, and tumor necrosis factor- α (TNF- α) are elaborated by epithelial cells, whereas IL-10 and IFN- γ are mostly made by infiltrating T cells. IL-10 promotes B-cell proliferation and IFN- γ heightens

expression of HLA-DR and La/SSB by exocrine glandular epithelial cells.

In SS, activated B cells produce increased amounts of immunoglobulins with autoantibody reactivity for IgG (rheumatoid factor), Ro/SSA, and La/SSB.¹³ Evidence suggests that the B cells may produce antibodies targeting the muscarinic M3 receptor.¹⁶ This is reminiscent of myasthenia gravis, an autoimmune disorder in which the target antigen is a postsynaptic receptor for acetylcholine at the neuromuscular junction. In SS, the blockade of the muscarinic (acetylcholine) receptor in exocrine tissue would diminish the production of secretions.

Several other possible explanations exist for the decline in exocrine secretions seen in SS. If tissue destruction is extensive, there may be insufficient tissue to produce secretions. However, total destruction of the salivary tissue is rarely seen in salivary gland biopsies in SS. Significant dryness may occur in individuals that have lost about half of the ducts and acini.¹⁵ Interestingly, patients with little or no tissue destruction may have significant or severe dryness. This suggests that immune-mediated mechanisms may directly or indirectly result in dryness in SS patients. Cytokines may interact directly with epithelial cells. Autoantibodies, other than those directed against muscarinic M3 receptors, could interfere with the nerve supply, resulting in diminished secretions out of proportion to tissue destruction.

Researchers have studied the pathogenesis and genetic factors in SS in a number of animal models, including the nonobese diabetic (NOD) mouse, the NOD.B10, NOD.SCID, and MRL/lpr mouse.^{1,9,15} The NOD mouse has an immunological profile and decrease in saliva production similar to that seen in human disease. Also, the transforming growth factor β (TGF- β) knockout mouse develops salivary and lacrimal gland exocrinopathy, suggesting a possible role for this cytokine in SS. TGF- β facilitates certain immune responses and acinar cell differentiation, and could possibly have a role in the early stages of SS.⁹ Recently, new mouse models for SS have been explored, including the NOD.H2h4 mouse, the IQI/Jic mouse, and the NFS/sld mouse model. In addition, BALB/c mice immunized with 60-kDa Ro (SS-A) peptides developed a disease similar to SS with lymphocytic infiltration of salivary glands and decreased saliva production.

CLINICAL SPECTRUM OF SS

The classifying manifestations of SS include oral and ocular symptoms and signs of dryness, the presence of autoantibodies, especially anti-Ro/SSA and anti-La/SSB antibodies, and a positive labial salivary gland biopsy. Masaki and Sugai have suggested that primary SS can be divided into three stages according to the extent of organ damage and the course of the disease.¹⁷ In stage I, representing about 45% of the patients, only sicca symptoms are present without systemic involvement. In stage II, affecting about half of the cases, lymphocytic organ damage occurs, which may affect the skin, lungs, kidney, liver, and hematological systems. In stage III, affecting about 5% of patients, malignant lymphomas occur. It is useful to think about the severity of the disease in terms of these stages. However, a caveat is that not all patients progress stepwise through these stages. Patients may be diagnosed in stage I or stage II or could present with lymphoma and features consistent with SS.

CLINICAL PEARLS

CLINICAL CONSIDERATIONS IN THE ASSESSMENT OF PATIENTS WITH SJÖGREN'S SYNDROME

- >> Sjögren's syndrome is a systemic autoimmune disease characterized by objective signs of ocular and oral dryness, focal mononuclear cell infiltrates in labial minor salivary gland biopsies, and anti-SS-A or anti-SS-B autoantibodies
- >> Salivary gland swelling that occurs in conjunction with meals is more likely to have an obstructive than an inflammatory cause
- >> When angular cheilitis is seen, examine the mouth and pharynx carefully for possible candidiasis
- >> Unlike rheumatoid arthritis, the arthritis of SS is generally nonerosive. An arthropathy similar to that seen in systemic lupus erythematosus (SLE) may occur
- >> Both primary SS and SLE have antinuclear antibodies. SS patients often have, and SLE patients may have, antibodies to SS-A. In primary SS, the double-stranded anti-DNA is negative, in contrast to SLE. Kidney disease in SS is mostly interstitial nephritis and renal tubular acidosis, whereas glomerulonephritis is more common in SLE. The cutaneous manifestations of SS patients are mainly dryness and vasculitic lesions, whereas malar rashes, discoid lupus, and maculopapular eruptions are more common in SLE
- >> The vasculitis of SS most often involves the lower limbs in dependent areas, and individual lesions tend to resolve within 48 hours. The vasculitis may occur as leukocytoclastic vasculitis, which tends to be associated with cryoglobulinemia. Vasculitis is often associated with peripheral neuropathy
- >> Peripheral neuropathy occurs in about 20% of patients and is easily missed since patients may not be aware of lower-limb sensory loss. Screening by testing sensation, particularly vibration sense, is useful
- >> Patients with purpura or cutaneous vasculitis, low serum C3 or C4 complement levels, and low peripheral blood CD4 T-cell counts, and possibly persistent salivary gland swelling, lymphadenopathy, and splenomegaly, are at higher risk for the development of lymphoma, and should be followed closely

OCULAR FEATURES

Precorneal tear fluid represents a complex biochemical mixture that includes water, electrolytes, mucins, antimicrobial proteins (e.g., lactoferrin and lysozyme), immunoglobulins, and growth factors (e.g., TGF- α). Three layers of precorneal tear film starting from the corneal surface are mucus, water, and oil layers.¹⁸ The precorneal mucus, protein, and aqueous components form a hydrated gel. Without the gel, KCS occurs. The barrier to fluorescein dye decreases, contrast sensitivity declines, and irregularity of the corneal surface increases. The outer layer of the precorneal tear film covers the hydrated gel, and is made by the meibomian gland; it consists of a complex mixture of nonpolar and polar lipids.

The relationships between dry eyes and the tear layers are shown in Figure 54.1. In SS, dry eyes result from aqueous tear deficiency (ATD). However, ATD is not pathognomonic of SS, but may occur because of other lacrimal gland diseases, lacrimal duct obstruction, and loss of reflex tearing. Dry eyes resulting from evaporative tear deficiency may be caused by meibomian gland disease, contact lenses, and blink abnormality. SS patients often experience a sensation of sand or grit in the eyes. Dry eyes may be assessed by performing a Schirmer's I test, where abnormal tear production is considered to be present when 5 mm or less of wetting of a standard rectangular strip of filter paper occurs in 5 minutes. In addition, a fluorescein tear film breakup time of less than 10 seconds, observed on slit-lamp examination, is consistent with dry eyes. The extent of staining of the ocular surface by Rose Bengal or other vital dyes can be evaluated using the van Bijsterveld scoring system. In the USA and UK, ophthalmologists commonly use lissamine green, since Rose Bengal staining tends to be more irritating to the eye. Keratinization may also be assessed as a measure of dryness of the ocular surface. Further evaluations of ocular dryness may include surface cytology, lacrimal gland biopsy, and, in a research setting, analysis of tear composition.

ORAL FEATURES

Often, patients with SS experience awareness of decreased saliva, oral dryness that interferes with eating, the need to drink liquids to facilitate the swallowing of dry foods, a chronic burning sensation, intolerance of spicy foods, and altered taste.¹⁹ Oral dryness can result in speech difficulties that may hamper social interactions. Patients with occupations such as teaching, that make demands on speech, may have to retire early. Patients should be asked about their current and past medications, since more than 400 medications have been reported to be associated with dry-mouth symptoms, including a number of commonly prescribed drugs for hypertension, depression, and insomnia.¹⁹ A history of radiation therapy for head and neck tumors should be sought, since this may produce severe oral dryness.¹⁹ Radioactive iodine for thyroid disorders also accumulates in exocrine glands, particularly the salivary glands, potentially resulting in oral dryness. Examination often shows erosions of the teeth and caries, as shown in Figure 54.2, especially at the gingival margins and on the incisal edges of the teeth. Soft-tissue changes are common. The tongue may become furrowed, and the mucosa dry, as shown in Figure 54.3, and sticky. Mucosal erythema and white patches are found in candidiasis, a common complication of dry mouth.¹⁹ When angular cheilitis is present (shown in Figure 54.4), candidiasis should be suspected. Decreased or absent saliva pooling can often be observed on examination. Dysphagia can be investigated by barium swallows or ultrasound studies, which may show esophageal dysmotility.

Major salivary enlargement glands may be observed, as shown in Figure 54.5. The parotid gland may displace the earlobe and the swelling may extend downward over the angle of the jaw. Medial to the angle of the jaw, submandibular salivary gland swelling may be visible or, more frequently, palpated. Tenderness of the glands is variable, and the swelling is often recurrent, thus distinguishing it from mumps. The salivary gland swelling of SS may be transient or chronic. Transient recurrent swelling of rapid onset occurring with eating or drinking suggests salivary duct obstruction. Causes of such obstruction include sialolithiasis and strictures of the duct.

Fig. 54.1 Causes of dry eyes.

Fig. 54.2 Dental erosions.

Fig. 54.3 Dry mouth.

MUSCULOSKELETAL FEATURES

Systemic rheumatic symptomatology may include fatigue, myalgias, arthralgias, low-grade fever, and lymphadenopathy.²⁰ Patients may develop a symmetrical polyarthritis that resembles rheumatoid arthritis. However, as in SLE, it is usually nondeforming. The arthritis of SS tends to respond well to standard treatments used in rheumatoid arthritis. These include nonsteroidal anti-inflammatory drugs, methotrexate, azathioprine, and other agents. The role, though, of TNF- α blockers in more severe cases of arthritis in SS patients is unclear. In so-called secondary SS, rheumatoid arthritis, or SLE, may occur and may begin before or after the onset of SS. Although an increased frequency of sicca

symptoms have been described in fibromyalgia, it is unclear whether fibromyalgia occurs more frequently in SS.

CUTANEOUS FEATURES

Dry skin occurs in about half of patients affected with SS.²¹ Sweating may be decreased. Pruritus may be associated with dry skin, and in some cases with the dysesthesia of peripheral neuropathy. Repeated scratching may result in hyperpigmentation, excoriations, and lichenification of the skin. In addition, palpable or nonpalpable purpura and petechiae occur in some patients, most frequently on the legs, in showers of lesions lasting up to 4 days. These lesions are histologically consistent with either leukocytoclastic vasculitis, which is typically associated with anti-Ro(SS-A) and La (SS-B), rheumatoid factor, antinuclear antibodies, cryoglobulins, hypocomplementemia, hypergammaglobulinemia, and

Fig. 54.4 Angular cheilitis.

Fig. 54.5 Parotid enlargement.

circulating immune complexes, or mononuclear inflammatory vasculopathy, which is not usually associated with seroreactivity and hypocomplementemia. Vasculitic lesions may also have the appearance of urticaria, erythema multiforme, erythematous macules, patches, or nodules, and digital ulcers. The presence of erythema nodosum should raise the suspicion of sarcoidosis.

NEUROLOGICAL FEATURES

Peripheral neuropathy occurs in about 20% of patients with SS and is most prominent in the lower limbs, and to a lesser extent the upper limbs.²² It is most often sensory. Trigeminal and other dermatomal

involvement may occur. Autonomic neuropathy may occur, and should be considered in patients with symptoms such as unexplained postural hypotension. In addition, involvement of the central nervous system has been described, and lesions have been noted in imaging studies. Peripheral neuropathy tends to be associated with vasculitis, although it may occur in the absence of vasculitis.

HEMATOLOGICAL FEATURES

Lymphoid malignancy is an important hematologic complication of SS. Amongst the rheumatic autoimmune diseases, SS has the highest frequency of B-cell lymphomas.^{2,13} Reported frequencies have varied. The early report of a 44-fold increase in the frequency of B-cell lymphomas among SS patients compared to the general population was not population-based. Subsequent estimates were lower;³ Theander et al. found about a 16-fold increased risk.² While as many as 10% of patients with SS may develop malignant lymphoma, a multicenter European study showed lymphoma in 4.3% of SS patients; these were mostly low-grade B cell lymphoma of the mucosa-associated lymphoid tissue (MALT) type.^{2,13}

What are the risk factors for the development of B-cell lymphomas in SS? A low CD4/CD8 T-lymphocyte ratio was recently reported as a risk factor in a longitudinal population-based study.² This increased risk of developing lymphoma in that study was only seen in patients who met the American European classification criteria for SS,² requiring either tissue inflammation or autoantibodies (anti-Ro/SSA or La/SSB). This illustrates the importance of case definition and subject selection in the interpretation of epidemiological studies of the risk factors for SS. Purpura or skin vasculitis and low C3 and low C4 were also risk factors in that study.² Others have suggested that parotid enlargement, lymphadenopathy, and splenomegaly are risk factors for the development of lymphoma. Although indolent MALT lymphomas are more often reported in SS, Theander et al. found that 58% had high-grade, diffuse, large B-cell lymphomas.²

Often cervical lymph nodes and salivary glands are involved. Although nonmalignant glandular swelling with reactive changes occurs more often, malignancy should be ruled out in patients with significantly or prominently swollen salivary glands or nodes in the neck. Diagnostic imaging, such as computed tomographic scans, needle aspirates for cytological and flow cytometric analyses, or biopsy should be considered.

RESPIRATORY FEATURES

Most patients with SS who have pulmonary involvement do not develop progressive disease.²³ Those who do may require more aggressive treatment with immunosuppressive agents such as azathioprine. Dry cough is not uncommon and is probably related to tracheal dryness and diminished mucus production.²⁴ The cough may also reflect hyperreactive airways in both primary and secondary SS. Smaller airways may be obstructed with minor abnormalities in pulmonary function tests, and lymphocytic infiltrates may be observed in bronchiolar walls. Mucosal biopsies and bronchoalveolar lavage show increased submucosal CD4 T lymphocytes. Interstitial pulmonary disease that is generally mild and rheumatoid-like pulmonary nodules may occur in SS. Metastatic carcinoma, granulomatous lesions, such as sarcoidosis, and other causes should be considered in the differential diagnosis and follow-up of such

THERAPEUTIC PRINCIPLES

TREATMENT OF SJÖGREN'S SYNDROME

- >> Sicca symptoms may be ameliorated by decreasing loss of moisture by evaporative loss from body surfaces (such as by using viscous artificial tears), coating dry surfaces with liquid (artificial saliva and tears), and stimulating existing exocrine tissue to increase secretions (muscarinic M3 agonists, such as pilocarpine and cevimeline)
- >> Local inflammation of the ocular surface can be treated with anti-inflammatory substances such as topical cyclosporine
- >> Systemic inflammation of SS is generally treated in a similar manner to systemic lupus erythematosus. Most commonly hydroxychloroquine and nonsteroidal anti-inflammatory drugs are used. In more severe cases, particularly with arthritis, various disease-modifying antirheumatic drugs, such as methotrexate, azathioprine, and other agents may be used. In the most severe cases brief treatment with glucocorticoids and in some cases cytotoxic agents (such as cyclophosphamide) may be used, such as in cases of life-threatening vasculitis
- >> Tumor necrosis factor blockers are best avoided as they do not appear to benefit patients with SS

nodules. Sarcoidosis manifestations include hilar adenopathy, elevated angiotensin-converting enzyme levels, and granulomatous lesions on salivary gland biopsy. Pleural effusions may be noted in primary SS, and may contain antibodies to SS-A, SS-B, and increased lymphocyte counts.

UROGENITAL FEATURES

Irritable bladder symptoms, including urinary frequency, are not uncommon.^{25, 26} Urinary frequency may also be caused by drinking excessive fluid to alleviate oral dryness. Renal manifestations include decreased ability to concentrate urine in about half of the cases, distal renal tubular acidosis in about 15%, nephrocalcinosis, renal stones and, less frequently, interstitial nephritis and glomerular disease. Urine pH is generally above 5.5 in renal tubular acidosis and the disorder is associated with systemic acidosis, which results in mobilization of calcium from bone, promoting osteoporosis and resulting in hypercalciuria. In addition, urinary citrate, which normally complexes a substantial proportion of urine calcium, is low. The risk of calcium phosphate stones is increased. Tubular proteinuria occurs in about half the SS cases. Glomerular disease occurs in about 2% of patients, especially in those with longer disease duration, and tends to be associated with cryoglobulins.²⁶ Patients with glomerulonephritis tend to have mixed cryoglobulinemia and low C4 levels in the serum.

Women with SS often have symptoms of vaginal dryness, which is commonly associated with dyspareunia.²⁷ Vaginal dryness may be the initial presenting symptom of SS. Obstetric complications in SS, including the risks of prematurity, pre-eclampsia, intrauterine growth

retardation, and fetal loss, tend to be related to concomitant autoimmune disease, mostly SLE. However, these problems do not appear to be increased in primary SS.²⁷ Since anti-SSA (Ro) antibodies occur in SS, there is a risk of congenital heart block, although the frequency is low.

THYROID

Thyroid disease, particularly hypothyroidism, is common in SS patients.²⁸ This has led to the impression that autoimmune thyroiditis may be a manifestation of SS. However, evidence for a convincing association is lacking. Ramos-Casals and coworkers found no significant differences in the prevalence of thyroid disease in SS patients compared with individuals of similar age and gender.²⁸

LABORATORY FEATURES

SS is frequently associated with positive tests for rheumatoid factor (90%), anti-Ro/SSA or anti-La/SSB (50–90%), and hypergammaglobulinemia.²⁰ Antinuclear antibodies occur in about 80% of cases. The 52-kDa Ro is more often associated with SS, while 60-kDa Ro appears to be more frequent in SLE. Autoantibodies that precipitate Ro/SSA are associated with systemic manifestations of the disease, including anemia, leukopenia, thrombocytopenia, purpura, cryoglobulinemia, hypocomplementemia, lymphadenopathy, and vasculitis.

Other autoantibodies occur in SS, including those directed against carbonic anhydrase, pancreatic antigen, α fodrin, 97-kDa Golgi complex, mitotic spindle apparatus, M3 muscarinic acetylcholine receptors, Fc γ receptors, and centromeres.²⁰ However, these autoantibody specificities are currently not used in the diagnosis and monitoring of the disease.

TREATMENT OF SJÖGREN'S SYNDROME

A general approach to SS is to educate patients on the disease and how best to cope with it, and to treat sicca symptoms and inflammatory manifestations. The treatment of sicca symptoms involves minimizing the loss of moisture from body surfaces, covering dry surfaces with liquid, as in the sipping of fluids and use of eye drops, and stimulation of existing secretory tissue with secretagogues, such as pilocarpine or cevimeline. The treatment of inflammation involves the use of drugs such as hydroxychloroquine, corticosteroids, methotrexate, azathioprine, and other immunomodulatory or immunosuppressive drugs.

PATIENT EDUCATION AND SELF-CARE

As in any chronic disease, it is important to help the patient develop strategies for self-management and coping with physical, mental, and social challenges associated with the condition. Patient education on the manifestations, course, prognosis, complications, and treatment of the disease and actions that they make take to minimize complications are extremely important.²⁰ Since there is often a lag of years before the diagnosis is made, acknowledging the patient's concerns is important.

SICCA SYMPTOMS

Keratoconjunctivitis sicca

Treatment includes tear replacement and conservation, and topical ocular and systemic medications.²⁹ Artificial tear eye drops are cellulose derivatives and are used frequently for symptoms of dry eyes. Since preservatives can irritate or damage the ocular surface and cause allergies, they are best avoided. Artificial tears in small individual dispensers lessen infections from bacterial contamination. Also, to reduce the risk of infection, patients should avoid rubbing the eyes and rinsing the ocular surface with tap water.

When artificial tears are insufficient to control symptoms, hydroxypropylcellulose pellets can be placed under the lower eyelids. Artificial tears are used to dissolve the pellets, which retain moisture in the eye. Ointments, which decrease evaporative tear loss, are used during the night, as these viscous materials may interfere with vision. Artificial tears can leave crusts on the eyelashes, and ointments may potentially obstruct meibomian glands. By washing eyelashes with baby shampoo, the development of blepharitis can be prevented or treated. Topical steroids, cyclosporine eyedrops, and intraocular androgens may be beneficial in the treatment of KCS. Evidence suggests that intraocular androgens may have a role in treating ocular inflammation and dryness. Systemic pilocarpine appears to improve ocular symptoms, and cevimeline has been approved for this indication. The role of systemic treatment for ocular inflammation of SS remains unclear.

When dry-eye symptoms are unresponsive to the above approaches, punctal plugs can be used. Collagen plugs dissolve over 2 days. Silicon plugs last longer and can be taken out if they result in epiphora. If the use of temporary punctal plugs improves the ocular surface without excessive tears, permanent occlusion can be achieved by punctal cautery.

Xerostomia

Frequent dental care is important.¹⁹ Daily topical fluoride use and antimicrobial mouth rinses may help to prevent caries in patients with reduced salivary flow. Medications that promote oral dryness may be exchanged for more appropriate ones. Artificial saliva and lubricants may ameliorate symptoms in some patients. Sugar-free chewing gum or candies may stimulate residual salivary secretions to ameliorate oral dryness. Patients should be counseled on an appropriate diet and the importance of limiting sugar intake. Humidifiers may decrease sicca symptoms. Problems with swallowing may be treated with oral moisturizers and lubricants, and through dietary modifications.

Secretagogues such as pilocarpine and cevimeline may enhance secretions in patients with sufficient exocrine tissue.³⁰ Usually, pilocarpine 5 mg orally four times a day is given, and the total daily dose does not generally exceed 30 mg. Adverse effects include increased sweating, feeling hot and flushed, as well as symptoms associated with increased bowel and bladder motility. When bronchospasm is present, caution must be exercised. Patients with adverse effects may benefit from one to three 5 mg doses per day at times to ameliorate symptoms at the most troublesome time of day. Cevimeline can also be used to treat dry mouth in a dosage of 30 mg orally three times daily. It is a muscarinic agonist similar to pilocarpine that enhances production of saliva, and possibly tears and other secretions. Cevimeline is contraindicated for patients with uncontrolled asthma, iritis, and narrow-angle glaucoma.

Oral candidiasis, a common complication of dry mouth in SS, is treated by sucking oral troches or vaginal suppositories of antifungal agents, such as nystatin or clotrimazole. Angular cheilitis may require topical antifungal agents.¹⁹ Bacterial parotitis should be treated with warm compresses, massage of the parotid gland, and, if necessary, antibiotics.

The exocrine or systemic inflammatory manifestations may be treated by various immunomodulatory drugs. Hydroxychloroquine is commonly used for milder systemic manifestations, such as rashes and arthritis. Whether or not hydroxychloroquine is effective for the exocrine manifestations is unclear, although serological measures improve in SS patients on this medication.^{31, 32} Drugs such as methotrexate, prednisone, azathioprine, and other immunomodulatory drugs tend to be used in patients with prominent systemic manifestations in an approach similar to that used to treat SLE.^{31, 33} However, few randomized, double-blind clinical trials have been performed to demonstrate whether or not these agents are beneficial in SS. Small underpowered, randomized, controlled trials of prednisone and azathioprine showed no benefit.^{31, 33} Despite the initial results of an uncontrolled trial of infliximab, subsequent investigations revealed no evidence that TNF- α blockade has any benefit in SS.³⁴

ORGAN INVOLVEMENT

Special attention is needed in the treatment of certain organ complications in SS. In patients with renal tubular acidosis, treatment with oral alkaline preparations containing sodium and potassium citrate in a dose of 1–2 mEq/kg per day is used to correct the acidosis and decrease the risk of stones. In addition, the urine calcium should be monitored and patients should receive potassium supplementation. Patients with renal tubular acidosis have increased mobilization of calcium from bone, which requires appropriate monitoring and treatment. Bronchodilators may be useful in patients with chronic cough, since SS is associated with increased airways reactivity. The management of thyroid disorders in SS patients is no different from that for those without the disease.²⁸ The arthritis of SS tends to respond well to standard treatments for rheumatoid arthritis. Cutaneous dryness is treated with lubricants and decreased frequency of bathing. Pruritus may be treated with mentholated lotions. Superficial vasculitis and dermatitis are managed with steroids. Vaginal dryness and dyspareunia may respond to water-soluble lubricants, and vaginal estrogen preparations may be beneficial in postmenopausal females.

FUTURE TREATMENTS

While advances continue in our understanding of SS, only symptomatic treatments have been specifically approved for the treatment of this debilitating disorder. Immunomodulatory treatments, replacement of destroyed salivary gland tissue by artificial salivary glands, and the possibilities for gene therapies are under active investigation.

Currently, there is great interest in a number of immunomodulatory treatments for SS.³⁵ Approaches specifically targeting B cells are the most active area. Candidate therapies include anti-CD20, anti-CD22, and anti BLYS antibodies. Rituximab, an anti-CD20 antibody, has been investigated in autoimmune diseases, including rheumatoid arthritis, SLE, and SS. A number of SS cases treated with rituximab have been reported and studies are currently in progress. Although rituximab has not been approved for the treatment of SS, apparently some clinicians

are already treating patients with severe SS with this drug, but the results of sufficiently large double-blinded, randomized, controlled trials are lacking.

Despite the lack of success with TNF- α blockers, antagonism of various cytokines, such as IL-6 and IFNs has the potential to emerge as new therapies for SS within the next decade. Given the observation that patients with SS display a type I IFN signature, it is possible that blockade of type 1 IFN might be explored for the treatment of SS.¹⁰

It is also possible that IFN- γ antagonists may have a role in the treatment of the disease. Apoptotic epithelial cells may release material containing RNA-binding proteins, such as Ro/SSA.¹⁰ If a way can be found to slow the rate of epithelial apoptosis in SS, this could theoretically be an approach to treatment. There is evidence that immune complexes containing Ro/SSA-anti-Ro/SSA are formed in SS, and can bind to Fc receptors on plasmacytoid dendritic cells, become internalized, and activate TLRs.¹⁰ It is therefore possible that blockade of Fc receptors, or TLR could be an approach toward controlling the disease. In addition, the modulation or destruction of dendritic cells and T cells may be considered as a novel therapeutic strategy. Modulation of cell traffic by targeting integrins and selectins is another possible approach for future treatment. Bone marrow transplantation may be discussed as a means to remove autoreactive cells and reconstitute a normal immune system.

Work continues on the development of adeno-associated virus (AAV) vectors for gene therapy.³⁵ Experiments have been conducted using cytokine genes in AAV vectors in animal models of SS. Aquaporins, particularly aquaporin 5, which transports water through salivary and lacrimal epithelial cells, may have a role in the pathogenesis of SS. It is possible that viral vectors containing aquaporins may be considered in the future as an intraductal treatment directed toward increasing the capacity for water transport in residual epithelial cells.

Hormonal therapies are also under consideration. Androgens and various estrogens have been investigated as interventions in animal models of SS.

Work studying the differentiation of glandular epithelial cells also continues. Possibly, bone marrow cells may be capable of differentiating into glandular epithelial cells. This may present a future therapeutic opportunity in which precursor cells might be induced to reconstitute damage to epithelial tissue. Finally, research continues in the area of tissue engineering, exploring whether salivary or lacrimal glands can be grown in vitro and implanted to facilitate the production of secretions.

Systemic sclerosis

John Varga, Fredrick M. Wigley

55

Systemic sclerosis (SSc) is a chronic multisystem connective tissue disease characterized by autoimmunity and inflammation, widespread functional and structural abnormalities in small blood vessels, and progressive fibrosis of the skin and visceral organs. Multiple cell types and their products interact to mediate the pathogenetic processes that underlie the diverse clinical manifestations of SSc.

■ PREVALENCE AND EPIDEMIOLOGY ■

Systemic sclerosis is a sporadic disease with worldwide distribution. Incidence estimates in the USA range from nine to 19 cases per million per year, and prevalence rates range from 28 to 253 cases per million. The only community-based survey of SSc yielded a prevalence of 286 cases per million population.¹ Age, gender and ethnicity are important factors determining disease susceptibility.² Like other connective tissue diseases, SSc is more prevalent in women, with the most common age of onset in the age range 30–50 years. The incidence of SSc is higher among African-Americans than in whites, and disease onset occurs at an earlier age. Furthermore, African-Americans are more likely to have diffuse skin involvement and pulmonary fibrosis, and to have a worse prognosis.

■ ETIOLOGY AND PATHOGENESIS ■

GENETIC FACTORS

Systemic sclerosis is not inherited in a mendelian fashion. Monozygotic and dizygotic twin pairs show a similarly low rate (<5%) of disease concordance.³ Nonetheless, 1.6% of SSc patients have a first-degree relative with the disease, representing a relative risk of 13, indicating an important role for genetic background in disease susceptibility. In contrast to other connective tissue diseases, HLA linkages with SSc are weak, although specific HLA haplotypes do associate with distinct autoantibody responses. Genetic

investigations in SSc have focused primarily on polymorphisms of candidate genes. Weak associations of specific single nucleotide polymorphisms (SNP) have been reported in genes involved in regulation of immunity and inflammation, vascular function, and connective tissue homeostasis.⁴

ENVIRONMENTAL FACTORS

Viruses and exposure to environmental and occupational agents and drugs have been implicated as potential etiologic factors. There are reports that patients with SSc have increased serum antibodies to human cytomegalovirus (hCMV). Furthermore, a study suggests that in a subset of SSc patients autoantibodies to topoisomerase-I recognize antigenic epitopes present on hCMV-derived proteins, providing some evidence that molecular mimicry may be a mechanistic link between hCMV infection and SSc. Evidence of human parvovirus B19 infection has also been presented. These studies need to be confirmed, and the etiologic role of virus in SSc remains conjectural. Although reports of apparent geographic clustering of SSc cases suggest shared environmental exposures, careful investigations have failed to substantiate these clusters. Epidemics of multisystem illnesses with features suggestive of SSc have been linked to contaminated rapeseed cooking oils in Spain (the toxic oil syndrome), and L-tryptophan dietary supplements in the USA (eosinophilia-myalgia syndrome). Although both of these apparently novel syndromes were characterized by chronic scleroderma-like skin induration, they showed clinical and pathological features clearly that distinguished them from SSc. An increased incidence of SSc has been noted among men with occupational exposure to silica, such as miners. Other occupational exposures linked with an increased risk of SSc include polyvinyl chloride, trichloroethylene and organic solvents. Drugs potentially implicated in SSc-like illnesses include bleomycin, pentazocine and cocaine, and appetite suppressants associated with pulmonary hypertension. The occurrence of SSc in women with silicone breast implants raised concern regarding a possible association, but careful subsequent epidemiologic investigations could not substantiate an increased risk.⁵

Fig. 55.1 Pulmonary arterial involvement. Significant intimal layer hyperplasia is seen, leading to narrowing of the vascular lumen. (Courtesy of Dr Anjana Yeldandi.)

PATHOLOGY

The characteristic pathological features of SSc are a noninflammatory vasculopathy involving small arteries and arterioles in multiple vascular beds and fibrosis of the skin and internal organs. Although patients with established SSc display pathological changes in the absence of inflammation, in relatively early-stage disease cellular infiltrates may be found in many organs. In the skin, the infiltrates are located predominantly around blood vessels and in the reticular dermis, and are composed primarily of CD4 T lymphocytes.

Vascular injury is likely to be the initial event in the pathogenesis of SSc. In patients with established SSc, widespread vascular lesions are found and are characterized by bland intimal proliferation in the small and medium-sized arteries. The heart, lungs, kidneys and intestinal tract are most prominently affected (Fig. 55.1). Vasculitic lesions are virtually never found. In late stages, perivascular fibrosis may be prominent.

Fibrosis is prominent in the skin, lungs, gastrointestinal tract, heart, tendon sheaths and perifascicular tissue surrounding skeletal muscle. Accumulation of homogeneous connective tissue composed of type I collagen, fibronectin, proteoglycans and other structural macromolecules in these organs leads to progressive disruption of tissue architecture, resulting in functional impairment. In the skin, fibrosis causes massive dermal expansion and obliteration of hair follicles, sweat glands and other skin appendages. Collagen fiber accumulation is prominent in the reticular dermis, and the process invades the subjacent adipose layer with entrapment of fat cells. In the lungs, patchy infiltration of the alveolar walls with lymphocytes, plasma cells, macrophages and eosinophils is seen in early disease. With established disease, fibrosis and vascular damage predominate, often coexisting in the same lesions. However, in patients with limited cutaneous SSc the vascular lesions may predominate. Intimal thickening of the pulmonary arteries, best seen with elastin stain, underlies pulmonary hypertension, and at autopsy is often associated with multiple pulmonary emboli and myocardial fibrosis.

Pulmonary fibrosis is characterized by expansion of the alveolar interstitium, with local accumulation of collagen and other connective tissue

proteins. Progressive thickening of the alveolar septa results in obliteration of the air spaces and honeycombing, and loss of pulmonary blood vessels. This process impairs gas exchange and contributes to worsening of pulmonary hypertension. In the gastrointestinal tract, prominent pathological changes can occur at any level from the mouth to the rectum. The esophagus is frequently involved, with fibrosis of the lamina propria, submucosa and muscular layers, and the development of characteristic vascular lesions. Replacement of the normal intestinal architecture results in disordered peristaltic activity, with gastroesophageal reflux and small bowel dysmotility, obstruction and bacterial overgrowth. Chronic gastroesophageal reflux leads to esophageal inflammation, ulcerations and stricture formation, and premalignant Barrett's metaplasia.

The heart is frequently affected, with prominent myocardial contraction band necrosis reflecting ischemia–reperfusion injury, and patchy areas of myocardial fibrosis. In the kidneys vascular lesions predominate, and glomerulonephritis is rare. Chronic renal ischemia is associated with shrunken glomeruli. Patients with scleroderma renal crisis show dramatic changes in small renal arteries, with reduplication of elastic lamina, marked intimal proliferation and narrowing of the lumen, often with microangiopathic hemolysis.

PATHOGENESIS

An integrated picture of the complex pathogenesis of SSc must account for the vasculopathy, deregulated cellular and humoral immunity, and fibrosis of multiple organs. As illustrated in Figure 55.2, a complex and incompletely understood interplay between these distinct processes initiates, amplifies and sustains tissue damage in SSc.⁶

Vascular involvement

It is currently thought that vascular injury may be the initiating event in the pathogenesis of SSc. Evidence of vascular involvement is an early and widespread feature, with important clinical consequences. Vascular endothelial cell injury is initially associated with functional alterations, with altered blood flow response to vasomotor or cold challenge, and altered production of and responsiveness to factors that mediate vasodilatation (nitric oxide and prostacyclins) and vasoconstriction (endothelins). Microvessels show increased permeability, enhanced transendothelial leukocyte migration, activation of fibrinolytic cascades and platelet aggregation culminating in thrombosis. Endothelial cells show increased expression of surface adhesion molecules and release endothelin-1, which further promotes leukocyte adhesion and smooth muscle cell proliferation. Ensuing intimal and medial hypertrophy and fibrosis of the adventitial layer leads to luminal narrowing. Combined with endothelial cell apoptosis, the process culminates in the characteristic striking absence of blood vessels seen on angiograms of the hands and kidneys of SSc patients with late-stage disease. In addition, the process of revascularization appears to be defective in SSc, possibly due to a defect in bone marrow-derived CD34⁺ circulating endothelial progenitor cells.⁷

Cellular and humoral immune responses

In the early stages of SSc, activated T cells and macrophages accumulate in skin and lung lesions, where they secrete important mediators, including transforming growth factor- β (TGF- β), cytokines and chemokines. These molecules can activate fibroblasts as well as endothelial

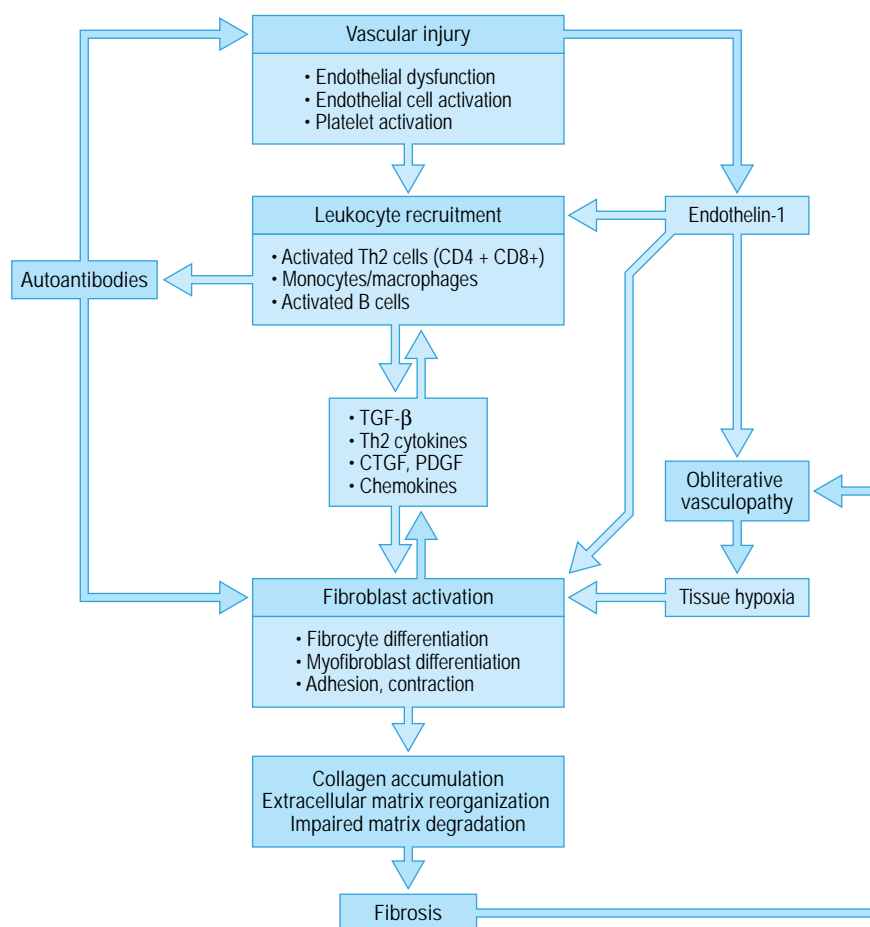

Fig. 55.2 Pathogenesis: fibrosis. Schema illustrating the interactions of cellular and molecular events involved in the pathogenesis of vascular and immune dysfunction resulting in fibrosis associated with systemic sclerosis.

cells, and initiate the fibrotic response. Because TGF- β in particular can induce its own production, as well as that of other growth factors such as connective tissue growth factor (CTGF), initial cytokine secretion associated with inflammation can result in sustained and amplified cytokine production and autocrine and paracrine signaling. The levels of TGF- β are elevated in the skin and lungs of patients with SSc, and receptors for TGF- β are over-expressed on lesional fibroblasts.

Virtually all patients with SSc have serum autoantibodies that are highly specific and mutually exclusive (see below). These SSc-specific autoantibodies show a strong association with individual disease phenotypes, and their titers may fluctuate with disease activity. Multiple mechanism(s) have been proposed to account for autoantibody generation in SSc. B cells from SSc patients are hyperresponsive.⁸ Additionally, it has been proposed that in SSc, specific self-antigens undergo post-translational modifications such as proteolytic cleavage, increased expression or altered subcellular localization that result in their recognition as nonself by the immune system. Although SSc-associated autoantibodies have well-established clinical utility as diagnostic markers, their contributions to disease manifestations remain uncertain. Emerging evidence

indicates that antibodies to fibroblasts and endothelial cells, platelet-derived growth factor (PDGF) receptor, and matrix metalloproteinases may potentially play a direct role in the tissue damage of SSc.

Fibrosis: Cellular and molecular components

Interstitial and vascular fibrosis in multiple organs, the hallmark of SSc, is characterized by replacement of normal tissue architecture with dense connective tissue, and is responsible for substantial morbidity and mortality. Fibroblasts and related mesenchymal cells are key effectors of fibrosis. Under the influence of appropriate signals such as TGF- β , CTGF, chemokines, endothelin-1 and hypoxia, these cells proliferate, migrate, elaborate collagens and other matrix macromolecules, adhere to and remodel connective tissue, secrete growth factors and cytokines and express surface receptors for them, and undergo transdifferentiation into contractile myofibroblasts. Together, these biosynthetic, contractile and adhesive functions enable fibroblasts to mediate effective wound healing. Whereas under physiologic conditions the fibroblast repair program is self-limited, in pathological fibrotic responses fibroblast activation is sustained and

amplified, resulting in exaggerated matrix accumulation and remodeling. Inappropriate fibroblast activation is the fundamental pathogenetic alteration underlying fibrosis in SSc. In addition to fibroblasts normally residing in tissues, bone marrow-derived mesenchymal progenitor cells also participate in the fibrotic response. For instance, peripheral blood mononuclear cells can differentiate into fibroblasts *in vitro*, and this process is enhanced by TGF- β . The factors that regulate mobilization of mesenchymal progenitor cells from the bone marrow remain largely unknown, including their trafficking to lesional tissue, and their *in situ* differentiation into matrix-producing adhesive and contractile fibroblasts.

Fibroblasts explanted from lesional SSc tissues display an abnormal phenotype indicative of autonomous activation characterized by enhanced synthesis of collagen and other extracellular matrix molecules, expression of α smooth muscle actin and cell surface adhesion molecules, and resistance to apoptosis. The activated scleroderma phenotype persists during the serial passage of lesional fibroblasts *in vitro*, and may be due, in part, to autocrine TGF- β signaling in these cells.⁹ Abnormalities in TGF- β pathways have been noted in SSc: lesional fibroblasts secrete TGF- β and exhibit TGF- β hyper-responsiveness due to elevated TGF- β surface receptors and latent TGF- β activation. Furthermore, SSc fibroblasts show evidence of activated intracellular signal transduction pathways that may contribute to the persistence and progression of fibrogenic responses.¹⁰ Targeted therapies that block TGF- β signaling and abrogate other fibrogenic pathways mediated by chemokines, endothelins and CTGF are under development.

CLINICAL FEATURES

Systemic sclerosis is highly variable in its clinical expression and thus represents a broad spectrum of disease. Whereas the disease process targets the skin, blood vessels, lungs, heart, gastrointestinal tract, kidneys and musculoskeletal system, subsets of patients exist with unique clinical features and distinct clinical outcomes. Raynaud's phenomenon is virtually universal in SSc, suggesting that perturbation of the terminal arteries of the circulation is a fundamental process that links the different subsets of the disease. Thickening of the skin distinguishes SSc from other rheumatic diseases (Table 55.1): scleroderma (hard skin) is the most specific and prominent physical finding. Patients vary in the expression of the skin changes, and are classified into two major subsets defined by the degree of clinically involved skin. In the diffuse skin variant called diffuse cutaneous SSc (dcSSc), fibrosis of the skin is widespread and the illness is more violent in expression, with rapid onset and an increased risk of serious and internal organ disease. In contrast, the limited skin variant called limited cutaneous SSc (lcSSc) presents with long-standing Raynaud's phenomenon, skin fibrosis limited to the fingers or distal limbs, and a generally indolent course. Limited SSc is less likely to be associated with organ failure or shortened life expectancy.

Although classification of SSc as diffuse and limited cutaneous is useful, disease expression is far more complex and several distinct phenotypes are recognized within each of the two subsets. For example, 10–15% of patients with lcSSc develop severe pulmonary arterial hypertension without significant lung fibrosis. Other patients develop systemic features of SSc without appreciable skin involvement, a phenotype that is termed systemic sclerosis sine scleroderma. Predictors of elevated mortality rates among SSc patients include diffuse skin disease and internal organ involvement, female gender, African-American race, and later age of disease onset.^{11, 12} Unique clinical phenotypes of SSc associate with

specific autoantibodies (Table 55.2). For example, anticentromere antibodies associate with lcSSc, whereas anti-topoisomerase-I antibodies associate with early interstitial lung disease. Some patients with SSc have 'overlap' features, where SSc coexists with clinical and laboratory evidence of another autoimmune disease, such as polymyositis, autoimmune thyroid disease, Sjögren's syndrome, polyarthritis, autoimmune liver disease or systemic lupus erythematosus (Table 55.2).

In contrast to SSc, the term 'scleroderma' is now properly used to describe patients with localized disease, a group of related fibrosing skin disorders that primarily affect children (Table 55.2). Localized scleroderma is infrequently associated with significant systemic

Table 55.1 Classification of systemic sclerosis

Diffuse cutaneous scleroderma – skin thickening on the trunk in addition to the face, proximal and distal extremities

Limited cutaneous scleroderma – skin thickening limited distal to the elbow and knee; may also involve the face and neck

CREST syndrome (C, subcutaneous calcinosis; R, Raynaud's phenomenon; E, esophageal dysmotility; S, sclerodactyly; T, telangiectasis)

Sine scleroderma – no apparent skin thickening but characteristic visceral organ involvement, vascular and serologic features

Overlap syndrome – criteria for SSc, coexisting with features of systemic lupus erythematosus, rheumatoid arthritis or inflammatory muscle disease

Mixed connective tissue disease – overlap syndrome with anti-U1RNP antibodies

Early disease – Raynaud's phenomenon with clinical and/or laboratory features of SSc; specific autoantibodies, abnormal nailfold capillaroscopy, finger edema and ischemic injury

KEY CONCEPTS

CLINICAL SUBSETS OF SYSTEMIC SCLEROSIS

Limited cutaneous scleroderma

- >> Distal skin sclerosis (sclerodactyly); trunk spared
- >> Severe Raynaud's phenomenon with digital ischemia
- >> Numerous telangiectasia
- >> Isolated pulmonary arterial hypertension

Diffuse cutaneous scleroderma

- >> Rapidly progressing widespread skin involvement
- >> Scleroderma renal crisis
- >> Interstitial lung disease
- >> Severe gastrointestinal dysmotility
- >> Cardiomyopathy

involvement. Morphea, a form of localized scleroderma, can occur as solitary or multiple lesions of expanding circular patches of thickened skin. Linear scleroderma presents as a streak of thickened skin, generally in one or both lower extremities. Linear scleroderma often involves the subcutaneous tissues, with fibrosis and atrophy of supporting structures, muscle and bone, and radiographs may show melorheostosis of the long bones. In children with linear scleroderma, the growth of affected long bones can be retarded. When the lesions cross joints, significant contractures of the affected joint can develop.

SYMPTOMS

Characteristically, the earliest symptoms of SSc are nonspecific and include fatigue, musculoskeletal distress (stiffness or pain) and feeling ill. Cold sensitivity and Raynaud's phenomenon occur early in the course and may be the only clinical clue. Symptoms of esophageal dysfunction with heartburn are common, and along with Raynaud's phenomenon may precede other manifestations of SSc by years. Visible capillary abnormalities at the nailfold (dilatation and loss or dropout of capillaries) are almost a universal finding in SSc, and precede other manifestations of the disease. An individual presenting with Raynaud's phenomenon, abnormal nailfold capillaries and the presence of a SSc-specific autoantibody can be diagnosed with SSc even before other manifestations are noted.¹³

DIFFUSE SSc

In general, patients with dcSSc have a short interval between Raynaud's phenomenon and the onset of other symptoms. Soft tissue swelling, intense pruritus and burning, and nonpitting edema are signs of the early inflammatory or 'edematous' phase of the diffuse cutaneous form of the disease. The skin of the fingers, hands, distal limbs and face are usually affected first, and more severely than other body areas (Fig. 55.3). Carpal

tunnel syndrome can be present as a consequence of soft tissue inflammation around the hands and wrists. Patients may note skin hyperpigmentation (patches or generalized tanning). Other early skin changes include vitiligo-like hypopigmentation ('salt and pepper' appearance), often on the chest or the back (Fig. 55.4). Escalating musculoskeletal symptoms are common, and are associated with muscle weakness and reduced joint mobility. Significant finger and hand/wrist disease limits the patient in performing simple chores or providing self-care.

The early edematous phase of dcSSc has prominent inflammatory features, with significant skin edema and erythema, and is associated with inflammatory cell infiltration in the dermis. After a period of weeks to months, the inflammatory phase evolves into the 'fibrotic' phase as the skin thickens, with thick folds on palpation and decreased skin flexibility. The fibrotic process starts in the dermis and is associated with loss of body hair, reduced production of skin oils, and a decline in sweating capacity as these cutaneous structures atrophy. Gradually the subcutaneous

- >> Gastroesophageal reflux with heartburn
- >> Swelling of the fingers and hands
- >> Musculoskeletal pain and stiffness
- >> Dilated nailfold capillaries
- >> Hyper- or hypopigmentary changes of the skin

Table 55.2 Autoantibody/phenotype association in SSc (From Harris ML, Rosen A. Autoimmunity in scleroderma: the origin, pathogenetic role, and clinical significance of autoantibodies. *Curr Opin Rheumatol* 2003; 15: 778–784, with permission)

Antigen	SSc Subtype	Clinical phenotype
Topoisomerase I (Scl-70)	Diffuse	Pulmonary fibrosis, cardiac involvement and cancer
RNA polymerase III	Diffuse	Severe skin involvement, renal crisis
Centromere proteins B, C	Limited (CREST)	Ischemic digital loss, sicca
U3-RNP (fibrillarin, Mpp 10, hU3-55K)	Diffuse or limited	Pulmonary arterial hypertension, cardiac and skeletal muscle involvement
B23	Diffuse or limited	Pulmonary arterial hypertension, Lung disease
Th/To-RNP	Limited	Lung disease, small bowel involvement, renal crisis
PM/Sci	Overlap	Myositis
U1-RNP	Overlap	SLE, myositis, polyarthritis

CREST, calcinosis; Raynaud's phenomenon, esophageal dysfunction, sclerodactyly, telangiectasia syndrome; RNP, ribonucleoprotein; SLE, systemic lupus erythematosus.

Fig. 55.3 Skin fibrosis in systemic sclerosis. Severe fibrosis of the skin of the hands and forearms causing joint contractures and skin ulcerations in a woman with diffuse cutaneous systemic sclerosis.

Fig. 55.4 Pigmentation changes in the skin. Vitiligo ('salt and pepper' appearance) of the involved skin in an African-American man with diffuse cutaneous systemic sclerosis.

tissue becomes affected, with atrophy of subcutaneous fat and fibrosis of underlying fascia, muscle and other soft tissue structures. During the fibrotic phase patients note pain, progressive loss of flexibility, distressing disfigurement and profound weight loss. Progressive flexion contractures of the fingers ensue. Other joints, including the wrist, elbow, shoulder, hip girdle, knees, and ankles, are also affected due to fibrosis of the supporting joint structures (Fig. 55.3). Thick ridges at the neck caused by firm adherence of the skin to the underlying platysma muscle interfere with neck extension. Tendon friction rub is a prominent crepitation that can be felt or even heard over tendons of the lower and upper extremity. Tendon friction rubs are due to fibrosis in the tissues surrounding the affected joints, and their presence is a marker of rapidly progressive and aggressive skin disease. Fibrosis of the skin of the face yields a characteristic facial appearance, with a diminished oral aperture, loss of facial expression,

vertical lines around the lips, loss of lip thickness and protrusion of the teeth. In the late stages of dcSSc involved skin may become thin or atrophic and bound down to underlying structures. Skin ulcerations often complicate the fibrotic, atrophic and avascular skin (Fig. 55.3).

The natural history of skin disease in SSc tends to be monophasic, and relapse after the edematous and active fibrotic phase is uncommon (<5%). The period from the first signs of skin involvement to its maximal extent is characteristically less than 3 years; cutaneous inflammation and progressive fibrosis gradually cease after 3 years, and the regression of skin involvement may occur. However, this timeframe is highly variable between patients, with many demonstrating rapid skin regression whereas others show chronically active disease over years. When the skin reaches its maximum involvement the skin disease appears to stop and dramatic recovery can occur, with a return to normal-appearing skin in those areas spared from severe end-stage fibrosis.

Whereas skin involvement is generally the most dramatic and visible manifestation of dcSSc, internal organ involvement occurs during the early active stage of advancing skin disease. Patients with dcSSc have a significant risk for interstitial lung disease, severe gastrointestinal dysfunction, SSc renal crisis, abrupt heart disease and recurrent digital ulcers during the active phases of the skin disease. In practical terms, this means that in dcSSc the initial 4 years is the period during which the systemic process is most active; if organ failure does not occur during this period, the systemic process may stabilize without further progression.

LIMITED CUTANEOUS SSc

The disease course in the limited cutaneous variant of SSc is more indolent and often relatively benign. After the onset of Raynaud's phenomenon, several years may pass before additional symptoms or signs are recognized. The most common non-Raynaud's symptoms in patients with lcSSc are those of upper gastrointestinal disease with dysphagia and gastroesophageal reflux. Dilated capillaries form visible erythematous vascular lesions (telangiectasia), seen most commonly on the fingertips, nailfold areas of the digit, palms, face, lips, and inside the oral cavity (Fig. 55.5). The CREST syndrome (subcutaneous calcinosis, Raynaud's phenomenon, esophageal dysfunction, sclerodactyly and telangiectasia) is a subtype of lcSSc with distinctive features, an overall good prognosis and associated with the presence of anticentromere antibodies. Subcutaneous calcinosis, due to deposition of calcium hydroxyapatite crystals, occurs commonly at sites of tissue ischemia and recurrent trauma, such as the fingertips, forearm or elbow.

Although significant internal organ disease occurs with lower frequency in patients with lcSSc, isolated pulmonary arterial hypertension (PAH) develops in 10–15% of patients and may be life-threatening.¹⁴ Severe Raynaud's phenomenon with macrovascular occlusive involvement occurs more frequently in lcSSc than in dcSSc, and may be associated with critical digital ischemia, ischemic ulcerations, gangrene, and a need for amputation. Overlap with other autoimmune syndromes, including the sicca complex, polyarthritis, cutaneous vasculitis and autoimmune liver disease, such as biliary cirrhosis, is seen primarily in the lcSSc subset of SSc.

RAYNAUD'S PHENOMENON

The skin has a unique vascular architecture designed to help maintain a stable central body temperature. This system has superficial and deep vascular plexuses connected by arteriovenous shunts that allow shunting

Fig. 55.5 Telangiectasia. Characteristic telangiectasia on the lip in a woman with limited cutaneous systemic sclerosis.

of blood away from the skin surface during exposure to cold. Temperature-activated receptor ion channels on the ends of unmyelinated nerve fibers located in the skin sense the ambient temperature and then send impulses to the dorsal root ganglion and the central nervous system. Following this input, efferent signals via the sympathetic nervous system directly determine vascular reactivity in the skin. Raynaud's phenomenon-associated increase in vascular tone is due in part to a defect in the vascular response to normal sympathetic signals. Recent studies find that α_2 -adrenergic receptors on smooth muscle cells of cutaneous vessels are responsive to cold and may be over-expressed in patients with Raynaud's phenomenon.¹⁵

Raynaud's phenomenon is clinically defined as cold- or emotional stress-induced vascular constriction of arteriovenous shunts, arterioles, and small arteries in the skin and tissues of the digits. Raynaud's phenomenon is manifested as pallor of the digits (the phase of complete loss of blood flow) followed by cyanosis of the skin (low flow with deoxygenated blood) and hyperemia as blood flow rebounds after rewarming the skin. Raynaud's phenomenon affects as much as 3–5% of the general population. In most cases it represents a genetic trait, with cold sensitivity due to abnormal cutaneous vessel reactivity. Raynaud's phenomenon is considered to be primary when there is no other associated disease state. In SSc, the disease targets blood vessels, and is one of many disease states that can alter the normal vascular response to ambient temperature and present with secondary Raynaud's phenomenon. Patients with SSc often have severe Raynaud's phenomenon, with multiple and often prolonged daily episodes associated with critical ischemia, leading to digital infarction or tissue gangrene. There is evidence that abnormal vascular reactivity in SSc is systemic, with recurrent bouts of vasospasm in the pulmonary, renal, gastrointestinal and coronary circulations.

Treatment must be individualized and adjusted according to the severity of the disease. Initial therapy should include avoidance of cold exposure and methods of stress reduction. The best-studied medications to treat Raynaud's phenomenon are the calcium channel blockers (e.g., nifedipine), and they remain the recommended first choice of therapy. Other vasoactive drugs reported to be helpful include the angiotensin II receptor blockers (e.g., losartan); the α_1 -adrenergic receptor blocker

prazosin, phosphodiesterase inhibitors including sildenafil, pentoxifylline, and cilostazol; serotonin reuptake inhibitors such as fluoxetine; nitrates including topical nitroglycerine; and intravenous prostaglandins.¹⁶ Bosentan, an endothelin-1 receptor inhibitor, was recently shown to reduce the occurrence of new digital ulcers in patients with SSc, but did not alter the frequency of Raynaud's events.¹⁷

GASTROINTESTINAL INVOLVEMENT

Gastrointestinal disease is the most frequent initial symptom after Raynaud's phenomenon. Patients with lcSSc and dcSSc are equally at risk. Gastrointestinal involvement is characterized by abnormal motility of the esophagus, stomach, small and large bowel and rectum. Pathological studies show that the smooth muscle (circular greater than longitudinal) of the bowel atrophies, without significant fibrosis, vascular injury or inflammation.¹⁸ Functional and pharmacological studies have shown that a neurogenic process precedes smooth muscle dysfunction. Virtually every patient with SSc demonstrates evidence of distal esophagus dysfunction. Clinically, this may present with dysphagia and dyspepsia typical of gastroesophageal reflux disease. Esophageal manometric evaluation reveals the characteristic triad of low or absent primary and secondary peristaltic activity in the distal esophagus, normal proximal esophageal (striated muscle) motility, and loss of lower esophageal sphincter tone. Complications such as reflux esophagitis, esophageal strictures, mucosal erosions and bleeding, Barrett's metaplasia or, very rarely, adenocarcinoma may develop.

Early satiety, bloating, nausea, periodic vomiting and decreased appetite with weight loss are common, and may be secondary to poor gastric emptying and retention of food and liquids in the stomach. Dilatation of mucosal capillaries is common in the gastrointestinal tract, particularly in the gastric antrum. This lesion, also called watermelon stomach, can be associated with recurrent occult gastrointestinal bleeding and significant anemia. Intestinal dysmotility may involve the small and large bowel. Patients may note a change in bowel habits, or may present with episodes of pseudo-obstruction with severe abdominal pain, bloating, abdominal distension and vomiting. Persistent diarrhea can be a manifestation of malabsorption of fats due to bacterial overgrowth in atonic small bowel, and can be associated with dramatic weight loss and malnutrition. In the late stages the bowel wall thins out and traps air (pneumatosis cystoides intestinalis). Wide-mouthed diverticuli develop in the colon or the bowel, and may rupture.

PULMONARY INVOLVEMENT

Lung disease is now the leading cause of death in patients with SSc and accounts for significant lifetime morbidity. Even in patients without respiratory symptoms, sensitive methods of pulmonary function testing reveal abnormalities, and 40% of SSc patients have clinically significant lung involvement. The most common and serious forms of lung involvement are interstitial lung disease (ILD) and pulmonary vascular disease. Risk factors for severe ILD include African-American race, diffuse skin involvement, and the presence of topoisomerase-I autoantibodies. Additional pulmonary manifestations of SSc include aspiration pneumonitis, pulmonary hemorrhage due to endobronchial telangiectasia, bronchiolitis obliterans with organizing pneumonia, pleural reactions and pneumothorax. The risk of lung cancer is increased in patients with SSc.

Interstitial lung disease

In patients with SSc, interstitial lung disease is most commonly characterized by the histologic pattern of non-specific interstitial pneumonitis (NSIP).¹⁹ Inflammatory alveolitis and subsequent tissue fibrosis cause a restrictive ventilatory defect and abnormal gas exchange. Patients with ILD may experience a rapid initial decline in lung function during the early period of active skin disease. About 20% of patients with ILD continue to progress to severe end-stage disease. In early disease, most patients have no respiratory symptoms. The most sensitive method to detect early lung disease is pulmonary function testing. Imaging by high-resolution computed tomography (HRCT) can be used to demonstrate fibrosis and ground-glass opacities, and can provide an indication of the activity of the process; the degree of fibrosis correlates with decline in forced vital capacity (FVC). Bronchoalveolar lavage (BAL) is sometimes performed to determine the level of activity, to predict outcome, and to rule out occult pulmonary infection. An increase in the total number of cells (mostly macrophages) in the BAL fluid, and an elevated proportion of neutrophils (>3%) and/or eosinophils (>2%), is considered a positive BAL result. In one study, 70% of untreated SSc patients who had positive BAL had a poor outcome, with a clinically significant decline in lung function.²⁰ Recent multicenter clinical trials comparing cyclophosphamide (oral or intravenous) against placebo demonstrated modest but statistically significant stabilization of lung function (FVC) in the active treatment group, along with improvement in skin score, respiratory symptoms, and a variety of clinical measures.^{21,21a} However, the clinical response was not durable after 1 year. The safety and efficacy of prolonged cytotoxic or immunosuppressive therapy remain to be evaluated.

Pulmonary arterial hypertension

Pulmonary arterial hypertension (PAH) is increasingly recognized as a frequent and severe complication of SSc, is detected in 12–15% of patients, it may occur as the sole pulmonary manifestation of the disease, or in association with ILD. The natural history of PAH is highly variable. In many patients with SSc it follows a relentless downhill course with right heart failure and significant mortality. Risk factors for PAH in SSc include limited cutaneous disease, late age at disease onset, history of severe Raynaud's phenomenon, and the presence of U1 RNP, anti-fibrillar or anti-B23 antibodies. Current therapy for SSc-associated PAH is focused on supportive care, reduction of cardiac workload and vasoactive drugs.²² Short-acting prostacyclin analogs, including intravenous (epoprostenol or treprostinil) or inhaled (iloprost) prostaglandins, have been in use for several years. More recent interventions include selective and nonselective endothelin-1 receptor inhibitors (bosentan, ambrisentan), and phosphodiesterase type 5 inhibitors (sildenafil). In relatively short-term clinical trials, each of these treatments has been shown to improve exercise tolerance and hemodynamics, with variable benefit on disease progression. Lung transplantation remains an option for selected SSc patients with severe lung disease.

CARDIAC INVOLVEMENT

Heart disease is more prevalent among patients with dcSSc than in patients with lcSSc. Most patients with heart involvement remain asymptomatic until the later stages, when heart failure or serious arrhythmia occur. Clinical evidence of heart disease, such as the presence of a

large pericardial effusion, is a poor prognostic indicator. Although generally asymptomatic, pericardial disease can cause typical pericarditis, and rarely significant hemodynamic compromise and tamponade. Myocarditis is less common but can be life-threatening. Severe cardiomyopathy is associated with evidence of polymyositis.²³

RENAL INVOLVEMENT

The most dreaded complication of SSc is acute renal involvement, called scleroderma renal crisis. It develops in 10–15% of patients, most commonly those with dcSSc, and is generally a relatively early (<3 years) complication of the disease.²⁴ The presence of tendon friction rubs, pericardial effusion, new unexplained anemia, and RNA polymerase III autoantibodies is associated with elevated risk of renal crisis. Several studies have indicated an association with recent corticosteroid use. Scleroderma renal crisis characteristically presents as malignant hypertension and rapidly progressive oliguric renal failure. Proteinuria, microhematuria, and evidence of a microangiopathic hemolytic process with thrombocytopenia are present. Patients with scleroderma renal crisis who present with a creatinine >3 mg/dL have a poor outcome, with permanent hemodialysis and high mortality. Prompt recognition and aggressive intervention with angiotensin-converting enzyme (ACE) inhibitors to achieve good blood pressure control before evidence of renal dysfunction significantly improves the prognosis.

MUSCULOSKELETAL COMPLICATIONS

Although musculoskeletal complaints are among the earliest symptoms of SSc, inflammatory erosive polyarthritis is uncommon. Joint involvement is usually due to fibrosis of the overlying skin, the supporting joint structures and the joint capsule itself. Flexion contractures associated with 'friction rubs' over tendons are typical of advanced dcSSc, most prominent over the ankles, knees, shoulders and wrists. Muscle weakness is common, and may reflect deconditioning or disuse, malnutrition and weight loss, as well as inflammatory myositis, muscle fibrosis and atrophy.

OTHER DISEASE MANIFESTATIONS

Many patients develop dry eyes and mouth (sicca complex). Unlike Sjögren's syndrome, in SSc these manifestations are due to fibrosis rather than lymphocytic infiltration of the minor salivary and tear glands. Furthermore, in SSc the sicca complex is associated with anticentromere, rather than Ro/SSA or La/SSB autoantibodies, a serological profile that also associates with a subset of patients with primary Sjögren's syndrome. Primary biliary cirrhosis is a rare complication of lcSSc, and is associated with antimitochondrial antibodies. Autoimmune hepatitis may also occur. Up to 20% of SSc patients are hypothyroid, owing to direct thyroid fibrosis or a consequence of autoimmune thyroiditis. The central nervous system is generally spared in SSc, but cases of trigeminal neuralgia have been reported. Erectile dysfunction frequently develops and is due to a combination of microvascular disease and corporeal fibrosis. In some patients with SSc, erectile failure is the initial manifestation of the disease. Because SSc affects every aspect of a patient's life and is disfiguring, it is not surprising that significant depression is common.²⁵ Chronic pain and the lack of social support are major causes of depression, and therefore vigorous pain control and antidepressant medication are important considerations in the management of SSc.

CLINICAL PEARLS

RECOMMENDED APPROACH TO THE EVALUATION OF A PATIENT WITH SYSTEMIC SCLEROSIS

- >> Determine skin score to define clinical subtype.
- >> Frequent clinical reassessment to define disease activity.
- >> Careful clinical history to evaluate for gastrointestinal dysmotility.
- >> Monitor for new onset hypertension: prevent renal crisis.
- >> Pulmonary function test: early detection of interstitial lung disease.
- >> Doppler echocardiography: screen for pulmonary arterial hypertension.
- >> Obtain serology profile to help predict clinical outcome.

THERAPEUTIC PRINCIPLES

TREATMENT OF SYSTEMIC SCLEROSIS

Organ-specific therapy

- >> Vasodilator therapy for Raynaud's phenomenon
- >> Proton pump inhibitor for gastroesophageal reflux
- >> ACE inhibitor for renal crisis
- >> Vasodilator therapy for pulmonary arterial hypertension
- >> Anti-inflammatory therapy for arthritis
- >> Immunosuppressive therapy for interstitial lung disease

Disease-modifying agents

- >> No ideal treatment available; immunomodulatory, anti-inflammatory, vasoactive and anti-fibrotic agents are used and/or under study

TREATMENT

Organ specific

The management of patients with SSc must be individualized and treatment decisions based on thorough assessment and careful monitoring. Most successful SSc treatments are directed to the specific organ(s) involved. Therapy is focused on an organ-specific disease process (e.g., ACE inhibitor in SSc renal crisis), or to aid a failing organ (e.g., proton pump inhibitors or metoclopramide for gastroesophageal reflux disease).²⁶ A recent placebo-controlled clinical trial investigated the efficacy of daily oral cyclophosphamide versus placebo in SSc patients with symptomatic early active alveolitis. The results showed that at 12 months of therapy cyclophosphamide was associated with stabilization of lung function, providing evidence that immunosuppressive therapy may be helpful in selected patients.²¹ Potentially safer immunosuppressive (e.g., mycophenolate mofetil), anti-inflammatory (e.g. anti-CCR2) or anti-fibrotic agents (e.g., imatinib) are currently being evaluated for the treatment of lung involvement in SSc.²¹

DISEASE MODIFICATION

To date, no drug or intervention has been shown to be effective and safe for modifying the disease course. Therefore, it is important to characterize the patient's clinical phenotype carefully and define the level of disease activity before deciding on therapy. For example, a patient with lcSSc who has no evidence of visceral organ involvement is likely to have a benign course requiring only symptomatic therapy (e.g., treatment of gastroesophageal reflux disease and Raynaud's phenomenon): disease-modifying drugs would not be indicated. It is also important to distinguish disease activity from severity or advanced cumulative organ damage. For example, a patient with late-stage dcSSc is unlikely to benefit from aggressive immunosuppressive or anti-inflammatory therapy. Intervention with currently available drugs should be initiated early, ideally during the edematous active inflammatory phase of the disease. It is during the early stages that immunosuppression, anti-inflammatory and anti-fibrotic agents have the greatest potential to control disease progression. Clinical

experience teaches that once the edematous phase of the disease shifts to the more indolent fibrotic phase, current treatments are largely ineffective to control the progression and tissue damage. Few well-designed controlled studies have been carried out for the treatment of early active disease; most reports are anecdotal uncontrolled experiences complicated by investigator bias and the highly variable natural course of SSc. Medications that have been used in SSc but appear to have little or no benefit include colchicine, DMSO, para-aminobenzoic acid, interferon (IFN)- γ , photopheresis, minocycline, and anti-tumor necrosis factor (TNF)- β agents. Controlled clinical trials have failed to provide evidence for the efficacy of D-penicillamine, a drug long in widespread use for SSc, or for recombinant relaxin.

Immunosuppressive drugs are used to control *early active* dcSSc because of the evidence that this is an autoimmune disease, initiated and/or propagated by an immune process. However, no rigorous trials have evaluated the efficacy of popular approaches to dcSSc. Drugs reported to have benefit include cyclophosphamide and mycophenolate mofetil. Additional reports suggest benefit with Cyclosporine, intravenous γ -globulin, anti-thymocyte globulin, thalidomide and methotrexate. The use of cyclophosphamide is limited by bone marrow suppression and bladder toxicity; mycophenolate mofetil by the issue of long-term immunosuppression; intravenous γ -globulin by its expense; Cyclosporine by frequent renal toxicity; thalidomide by skin rashes and peripheral neuropathy; and methotrexate by its potential to induce or exacerbate liver or lung fibrosis. Treatments targeting B cells with rituximab are under consideration. Multicenter clinical trials of immunoablative therapy with high-dose cyclophosphamide, alone or with radiation, followed by stem cell rescue, are in progress. High-dose cyclophosphamide without stem cell rescue is also under study. The use of novel biologic agents such as anti-cytokines (TGF- β), anti-chemokines (CCR2) or inhibitors of growth factors (CTGF) is being explored. Physicians are encouraged to refer patients with early dcSSc to specialty centers focusing on clinical trials.

OTHER SCLERODERMA-LIKE FIBROSING DISEASES

Several disorders can cause skin fibrosis and mimic SSc or scleroderma.²⁷ These include localized forms of scleroderma, eosinophilic fasciitis, scleromyxedema (papular mucinosis) and scleredema (Table 55.3).

Table 55.3 Differential diagnosis of SSc and scleroderma

Disorders characterized by similar presentations

Systemic lupus erythematosus
Sjögren's syndrome
Rheumatoid arthritis
Polymyositis/dermatomyositis
Primary Raynaud's phenomenon

Disorders characterized by similar visceral features

Primary pulmonary hypertension
Primary biliary cirrhosis
Idiopathic intestinal hypomotility
Idiopathic pulmonary fibrosis
Malignant hypertension

Disorders characterized by skin thickening

Scleromyxedema
Scleredema (of Buschke), diabetic scleredema
Nephrogenic fibrosing dermatopathy
Eosinophilic fasciitis/diffuse fasciitis with eosinophilia
Eosinophilia-myalgia syndrome
Generalized morphea
Chronic graft-versus-host disease
POEMS syndrome
Amyloidosis
Carcinoid syndrome
Pentazocine-induced scleroderma
Diabetic digital sclerosis
Vinyl chloride disease
Toxic oil syndrome
Bleomycin exposure
Werner's syndrome
Phenylketonuria
Porphyria cutanea tarda
Vibration white finger syndrome
Chronic reflex sympathetic dystrophy

A novel syndrome labeled nephrogenic fibrosing dermatopathy has been described in patients with end-stage renal disease.²⁸ Because many patients with this syndrome have evidence of visceral organ fibrosis in addition to skin involvement, 'nephrogenic systemic fibrosis' has been proposed as an alternate name. SSc can be distinguished from these scleroderma-like fibrosing conditions by its characteristic clinical, pathological and laboratory features. These include evidence of widespread vasculopathy with abnormal skin capillaries and Raynaud's phenomenon, the characteristic distribution pattern of skin changes and typical dermatopathological features, the unique pattern of visceral organ involvement, and the presence of SSc-specific serum autoantibodies.

The idiopathic inflammatory myopathies (IIM) – dermatomyositis (DM), polymyositis (PM), and inclusion body myositis (IBM) – constitute the largest subgroup of the acquired myopathies. They are a heterogeneous group and are rare among immunologic illnesses. However, the IIM share many clinical features and laboratory abnormalities, including related autoantibodies, and are closely related to major autoimmune diseases. Because their presentation and major clinical manifestations are weakness and/or rash, the differential diagnosis necessarily includes many more common diseases familiar to neurologists and dermatologists.

CLINICAL FEATURES

The clinical hallmark of polymyositis and dermatomyositis is the gradual onset over weeks to months of symmetric proximal muscle weakness. In some cases, myalgia may be the presenting or most bothersome symptom, but more often the patient is evaluated for the physical limitations imposed by weakness: difficulty arising from a low chair or bed, or combing and brushing hair. Rash is the first feature in a considerable proportion of patients who have dermatomyositis, but muscle weakness usually follows within a few months. A subset of patients with dermatomyositis, clinically amyopathic dermatomyositis (C-ADM), may present only with rash in the absence of muscle weakness throughout the course of their illness. These patients are also at risk for pulmonary involvement, as are those with classic DM. The prevalence of interstitial pneumonitis in C-ADM has not yet been determined; however, it may approach 5–10% (compared to 40% of patients with classic DM) based on an estimate made from the current published literature.¹ Arthritis, Raynaud's phenomenon, fever, or lung disease presenting as cough or dyspnea may dominate the clinical picture. Cardiac and gastrointestinal symptoms other than dysphagia in severe cases are rarely early manifestations. Renal and central nervous system (CNS) involvement are almost never a part of the IIM.

Some of the rashes of dermatomyositis are virtually pathognomonic; others are not disease specific (Fig. 56.1). The heliotrope rash, a violaceous discoloration of the eyelids, is sometimes no more than a line along the margin of the upper lid, but may also affect both upper and lower lids completely, and may be associated with edema mimicking thyroid disease.

A reddish, sometimes raised and/or scaly eruption over the metacarpophalangeal joints is known as Gottron's papules. In more advanced cases, the metatarsophalangeal joints, elbows, knees, and malleoli show a similar rash. Both heliotrope and Gottron's rashes can occur rarely in cases of frank systemic lupus erythematosus (SLE) without muscle involvement. Other common rashes include a flat red blanching eruption of the upper chest (often in a V distribution), the upper back (where a shawl would touch), and sometimes the extensor surfaces of the upper arms and thighs. Another rash that mimics the malar rash of lupus on the face may be present, but, in contrast to lupus, does not spare the nasolabial folds. Although found on sun-exposed parts of the body, these rashes are often not photosensitive in nature. As in other connective tissue diseases, nailfold capillary dilatation and infarcts and cuticular overgrowth occur. A roughening and cracking of the radial sides of the fingers and the palm, resembling a condition found in people who labor with their hands (mechanic's hands), is characteristic of a subset of myositis patients with the 'antisynthetase syndrome'.

CLASSIFICATION

In the past 40 years, several investigators have proposed diagnostic classification criteria for IIM. For clinicians, the criteria proposed by Bohan and Peter^{2,3} three decades ago remain the most familiar and accepted definitions of PM and DM. They combine clinical, laboratory, electrodiagnostic, and pathological features. These criteria currently serve as the gold standard for clinical diagnosis and for inclusion in clinical trials. However, they are limited by their poor specificity in distinguishing PM from other entities, including late-onset muscular dystrophies. The resultant misclassification limits the homogeneity of the patients included in previous observational and interventional studies. Additionally, the Bohan and Peter criteria completely omit the diagnosis of IBM, the most frequent type of IIM in patients over 50 years of age.⁴

Additional classification criteria have been proposed by Tanimoto et al.⁵ and by Targoff et al.⁶ (Table 56.1), but neither classification has been widely used. The Targoff classification scheme suggests the incorporation of MRI, but the sensitivity and specificity of this scheme have not been

Fig. 56.1 Dermatomyositis rash. **(A)** In addition to the heliotrope rash on the eyelids of this patient with dermatomyositis, there is a flat red rash on the nose and cheeks. **(B)** A raised shiny red rash – Gotttron's papules – is apparent on the interphalangeal and the second and third metacarpophalangeal joints of this man with dermatomyositis.

KEY CONCEPTS

DEFINITION AND INCIDENCE OF IDIOPATHIC INFLAMMATORY MYOPATHIES (IIM)

- >> Polymyositis, dermatomyositis, and related inflammatory muscle diseases are called IIM.
- >> Indistinguishable muscle inflammation may accompany other autoimmune connective tissue diseases or limb girdle muscular dystrophies.
- >> The annual incidence in the USA is 5–10 cases per million. DM and PM are more common in women than men in all age groups; IBM is more common in men.

KEY CONCEPTS

CHARACTERISTIC HALLMARKS OF INFLAMMATORY MYOSITIS

- >> The clinical hallmark is proximal limb and neck weakness, rarely associated with muscle pain.
- >> The laboratory hallmarks are elevated serum levels of creatine kinase (CK), aldolase, lactic dehydrogenase, and the transaminases, and a characteristic pattern ('irritable myopathy') on electromyography (EMG). Elevated serum levels of autoantibodies are common.
- >> The pathologic hallmarks are focal muscle necrosis, degeneration, regeneration, and inflammation.

validated.⁵ The Tanimoto criteria lack quantification or specific requirements for satisfying some criteria, and do not include MRI.⁶ Separate classification criteria systems for IBM have been devised (Table 56.2), but characteristic muscle biopsy changes remain the defining feature in IBM.

It has been useful for some purposes to divide cases into groups: polymyositis, dermatomyositis, juvenile myositis, myositis associated with another connective tissue disease (usually systemic sclerosis, SLE, or Sjögren's syndrome), cancer-associated myositis (usually cases in which the diagnoses are made within 6–12 months of one another), inclusion body myositis, and a miscellaneous group that includes such rare entities as eosinophilic myositis (Table 56.3). This classification has allowed recognition of unique clinical and pathogenetic features and response to therapy. In the case of cancer-associated myositis, a more rational approach to workup based on recognition of groups at risk is now possible.

Autoantibodies unique to myositis – the so-called 'myositis-specific autoantibodies' – have allowed a useful alternative classification (Table 56.4). For example, patients with antibodies to one or another of a group of enzymes – the aminoacyl-tRNA (transfer RNA) synthetases, of which Jo-1 is the best known – have a characteristic syndrome that usually includes

interstitial lung disease, nondeforming inflammatory arthritis, fevers, mechanic's hands, and Raynaud's phenomenon, in addition to myositis. Those with antibodies to the signal recognition particle (anti-SRP) have severe disease of abrupt onset, often in the autumn, unaccompanied by rash. Recent work has shown that cardiac involvement is less common and survival is better in patients with anti-SRP than has previously been reported.⁷ Those with antibodies to the nuclear antigen Mi-2 almost always have the V and shawl rashes and cuticular overgrowth in addition to myositis. Each of the different autoantibody-associated groups also has a predominant histocompatibility type and clinical course (Table 56.4).²

Inclusion body myositis (IBM) is becoming increasingly recognized. The diagnosis of IBM is important because, unlike patients with other inflammatory myopathies, those with IBM rarely improve in strength with immunosuppressive therapy. Patients with IBM tend to be older than others with myositis, and in contrast to patients with PM and DM, who are predominantly women, IBM patients are commonly men. They have gradual, painless, progressive weakness and focal atrophy that develop over years, and may complain of frequent falls. The forearms of

Table 56.1 Current idiopathic inflammatory myopathy: diagnostic criteria

Bohan and Peter criteria	Targoff proposed criteria	Tanimoto proposed criteria
1. Symmetrical proximal muscle weakness	1. Symmetrical proximal muscle weakness	1. Symmetrical proximal muscle weakness
2. Skeletal muscle enzyme elevation	2. Skeletal muscle enzyme elevation	2. Skeletal muscle enzyme elevation
3. Abnormal EMG*	3. Abnormal EMG*	3. Abnormal EMG*
4. Muscle biopsy abnormalities	4. Muscle biopsy abnormalities**	4. Muscle biopsy abnormalities**
5. Typical skin rash of DM***	5. Typical skin rash of dermatomyositis***	5. Typical skin rash of dermatomyositis***
	6. One of the myositis specific antibodies (MSAs)	6. Muscle pain
	7. MRI may substitute for criterion 1 or 2	7. Positive Anti-Jo-1 antibody
		8. Nondestructive arthritis/arthralgia
		9. Systemic inflammatory signs†

*Polyphasic, short, small motor-unit potentials; fibrillation, positive sharp waves, increased insertional irritability; bizarre, high-frequency, repetitive discharges.
 **Degeneration/regeneration, perifascicular atrophy, necrosis, phagocytosis, fiber size variation, and mononuclear inflammatory infiltrate.
 ***Gottron's sign, heliotrope rash.
 †fever > 37° C, elevated CRP, elevated ESR > 20 mm by Westergren method.

For the Bohan and Peter criteria
 Possible PM = any two of the first four criteria; Possible DM = criterion 5 (rash) + any two criteria
 Probable PM = any three of the first four criteria; Probable DM = criterion 5 (rash) + any three criteria
 Definite PM = all four of the first four criteria; Definite DM = criterion 5 (rash) + all four other criteria

For the Targoff criteria
 Possible IIM = any two criteria
 Probable IIM = any three criteria
 Definite IIM = any four criteria
 MRI results consistent with inflammation may be substituted for criterion 1 or 2

For the Tanimoto criteria
 Rash plus at least four of the other eight items = DM
 Four of the items excluding rash = PM
 (There are no definite/probable/possible categories)

these patients exhibit a scalloped appearance, attributed to muscle atrophy. There are few signs of disease outside the skeletal musculature. Difficulties with swallowing can be a complaint of patients with any inflammatory myopathy, and are frequently a major problem in patients with IBM. The creatine kinase (CK) and other skeletal muscle-associated serum enzymes are normal in about one-quarter of patients with IBM, and only moderately elevated in the remainder. The electromyogram in IBM frequently demonstrates both myogenic and neurogenic features secondary to the effective denervation of some muscle cells by inflammation and necrosis.

Proposed criteria for the diagnosis of IBM rely on both pathologic and clinical features. In the clinical setting of an inflammatory myopathy, the presence on light microscopy (with confirmation by electron microscopy) of the characteristic inclusions or rimmed vacuoles is diagnostic. The origin of the vacuoles in IBM has been the focus of investigation and remains a source of speculation. Among the inflammatory myopathies, IBM is distinguished by substantial numbers of rimmed cytoplasmic vacuoles with tubulofilamentous material within myofibers. A variety of proteins have been found by immunohistochemistry in the muscle cells in IBM, including ubiquitin, β -amyloid precursor

protein, phosphorylated τ , and the transcription factor NF- κ B, but it is not yet possible to tie them to the pathogenesis of the illness.⁸ The infiltrates in the muscle of patients with IBM are composed predominantly of CD8 lymphocytes, closely resembling those found in the inflammatory infiltrate in the muscles of patients with polymyositis.⁹ There may be increased expression of HLA class I molecules in the muscle of patients with IBM.

IBM must be distinguished from other myopathies because of its chronic nature. These include acquired myopathies, such as those caused by toxins, and genetically determined myopathies, such as some muscular dystrophies and the metabolic myopathies. There are several important differences between IBM and these other myopathies. The separation, however, is not as defined as might be anticipated. Although some of the familial forms of IBM have a distinctive clinical presentation, often early in life, there have been several families with the typical late onset and inflammatory picture of the presumed sporadic cases. Several genetic loci have been identified in familial IBM, so it will be important to assess any identified mutations in familial IBM-associated genes in sporadic cases.¹⁰ A further complexity is that IBM has been described decades after typical dermatomyositis.

Table 56.2 Diagnostic criteria for inclusion body myositis**IBM diagnostic criteria****I. Diagnostic classification****Definite IBM**

Patients must exhibit all muscle biopsy features.* None of the other clinical or laboratory features are mandatory if muscle biopsy features are diagnostic.

Probable IBM

If the muscle biopsy shows inflammation and vacuolated fibers without other pathologic features of IBM, then a diagnosis of probable IBM can be given if the patient exhibits the characteristic clinical (II.A. 1,2,3) and laboratory (II.B. 1) features

II. Characteristic feature**A. Clinical features**

1. Duration of illness >6 months

2. Age of onset > 30 years

3. Muscle weakness

Must affect proximal and distal muscles of arms and legs and patient must exhibit at least one of the following:

Finger flexor weakness

Wrist flexor>wrist extensor weakness

Quadriceps muscle weakness

B. Laboratory features

Serum CPK<12 times the upper limit of normal

Muscle biopsy

Inflammatory myopathy characterized by mononuclear cell invasion of necrotic muscle fibers

Vacuolated muscle fibers

Either

(i) Intracellular amyloid deposits or

(ii) 15–18 nm tubulofilaments by electron microscopy

Electromyography must be consistent with features of an inflammatory myopathy

*Invasion of nonnecrotic fibers by mononuclear cells, vacuolated muscle fibers, and intracellular (within muscle fibers) amyloid deposits of 15–18 nm tubulofilaments.

Table 56.3 Traditional classification of idiopathic inflammatory myopathies

Type I	Primary idiopathic polymyositis
Type II	Primary idiopathic dermatomyositis
Type III	Dermatomyositis or polymyositis associated with malignancy
Type IV	Childhood dermatomyositis or polymyositis
Type V	Myositis associated with another connective tissue disease
Type VI	Inclusion body myositis
Type VII	Miscellaneous: eosinophilic myositis, localized nodular myositis, etc.

Table 56.4 Clinical features associated with myositis-specific autoantibodies

Autoantibodies	Characteristic clinical features
Anti-Jo-1 and other antisynthetases	Relatively acute onset of myositis, frequent interstitial lung disease, fever, Raynaud's phenomenon, arthritis, mechanic's hands, moderate response to therapy, persistent disease. Patients sometimes meet criteria for SLE or RA, but muscle disease or lung disease dominate the clinical picture and prognosis
Anti-SRP	Very acute onset of myositis, often in autumn, severe weakness, no rash, palpitations, females predominate, poor response to therapy
Anti-Mi-2	Relatively acute onset of myositis, classic dermatomyositis rashes with V sign and shawl sign, cuticular overgrowth, good response to therapy

SRP, signal recognition particle.

ETIOLOGY

IMMUNOLOGIC CLUES TO ORIGIN

The implications of myositis-specific autoantibodies that bind to and inhibit the function of native human enzymes involved in the formation of new proteins are tantalizing and probably significant. These autoantibodies appear to develop before symptomatic weakness or serum creatine kinase (CK) elevation, suggesting a close link to an initiating factor. Some of the clinical features, such as fever, arthritis, and lung disease, and the apparent seasonality in onset of disease in patients with anti-SRP, are reminiscent of some viral infections. In patients with autoantibodies against one of the aminoacyl-tRNA synthetases, such as Jo-1 (histidyl-tRNA synthetase), the possible connection to a viral inciting agent appeared compelling, as certain picornaviruses, which are closely related to viruses long suspected of causing myositis, such as Coxsackie viruses, can mimic tRNA in acting as a substrate for an aminoacyl-tRNA synthetase.¹¹ Direct proof connecting picornaviruses to human myositis, however, has not been obtained.¹² A rare example of a viral myopathy seen in conjunction with the West Nile Virus (WNV) has been observed.^{13,14} Symptoms in addition to the neurological manifestations included a myositis characterized by a T-lymphocyte infiltration of nerve fibers, leading the authors to conclude that the virus may reach the central nervous system via peripheral nerves. There were muscle fiber necrosis, atrophy, and inflammation with an exclusive T-cell infiltration with a slight predominance of CD4 over CD8 cells and with scattered CD68⁺ cells. There were no inflammatory changes seen in blood vessels and muscle septa, and WNV antigens were not detected by immunohistochemistry. A variety of other nonspecific immunologic abnormalities occur in the IIM.

DRUGS AND TOXINS

A large number of environmental agents have been associated with myopathies. Sometimes the illness strikingly resembles the spontaneous disease. D-Penicillamine, for example, can induce a variety of autoimmune phenomena, including an inflammatory myopathy that closely resembles polymyositis. A number of drugs can also produce myopathies that can be clinically confused with IIM but are histologically distinct. This large group includes corticosteroids, zidovudine (AZT), and 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors. In corticosteroid-induced myopathy, type II muscle fiber atrophy is prominent on muscle biopsy and weakness improves when the dose is lowered. AZT produces a characteristic mitochondrial myopathy. The myopathy associated with HIV infection can be distinguished from that caused by AZT by muscle biopsy, as characteristic mitochondrial abnormalities are found in the latter. The HMG-CoA reductase inhibitors produce elevated CK and myalgias in some patients. Rhabdomyolysis has been reported, but is rare. The antimalarial drugs chloroquine and hydroxychloroquine produce a vacuolar myopathy, possibly by raising the intralysosomal pH so that the acid cathepsins that digest waste products in the lysosome are inoperable, and waste products accumulate in vacuoles. For most other drugs, the mechanism of toxicity is unknown. The claims that injections of type I collagen or silicone breast implants can cause inflammatory myositis were initially unsupported by epidemiological data, but recent work by NIH investigators concluded from a case series study that women who develop IIM after receiving silicone breast implants constitute an immunologically distinct group of patients. Those

with silicone implants and myositis had a unique association with HLA-DQA1*0102 and a decreased frequency of DRB1*0301 compared to patients with IIM in the absence of implants.¹⁵

BACTERIAL AND PARASITIC DISEASES

Certain parasitic diseases can produce an illness by direct invasion of muscle. Weakness, fever, and eosinophilia are usually present. Bacterial pyomyositis is uncommon in North America, but occurs more commonly in other parts of the world. It is attended by the signs of local infection and is often asymmetrical. A recent report, however, details two cases of pyomyositis initially diagnosed as polymyositis. Patients presenting with disseminated pyomyositis may be difficult to distinguish clinically from those with IIM, especially in immunosuppressed individuals who may not mount a systemic response.¹⁶

PATHOGENESIS

The precise mechanisms of cell damage and death in the IIM are unknown. Apoptosis is absent in IIM biopsies, but infiltrating CD8 T cells in polymyositis do appear to release perforin and granzyme into targeted muscle cells. After damage, a muscle fiber, which is a syncytium, can regenerate. Initially, on light microscopy one can appreciate loss of striations leading to a homogeneous appearance, fiber size variation, atrophy, and centralization of the nuclei. In the inflammatory myopathies, mononuclear cell invasion is a primary method of destruction. Macrophages and cytotoxic T cells invade the myofibers. The myocyte cytoplasm in the region of the invaginated cells appears vacuolated and swollen. Other regions of the same cell may show intense regeneration, as seen histologically by aggregates of nuclei with prominent nucleoli and fiber splitting. Thus, degeneration and regeneration may coexist in the same fiber.

The inflammatory milieu in inflamed muscle has been studied. Proinflammatory cytokines were not always detectable, although the chemokines MIP-1 α and RANTES were present in most biopsies,^{17,18} and IL-1 β was also usually present.¹⁹ TGF- β is constitutively present in muscle. The muscle cells and inflammatory cells present in IIM often have co-stimulatory molecules on their surfaces, reinforcing the picture of a direct interaction between them.²⁰ Tissue culture observations of muscle cells have demonstrated that they can both produce and respond to a considerable range of cytokines.

Engel and colleagues⁹ have demonstrated several important pathologic distinctions between dermatomyositis and polymyositis, and have suggested that, in dermatomyositis, the initial point of injury may be the capillaries. A model of disease has been proposed in which capillaries are primarily damaged and myocytes are secondarily involved. Complement and immunoglobulins may be found in the walls of the capillaries even where the remainder of the muscle is normal. The membrane attack complex of complement deposits there, and endothelial cells are swollen and pale. Even in unaffected regions of muscle, special staining reveals a marked decrease in capillary numbers.²¹ More advanced changes include microtubular endothelial inclusions and microvacuoles. Evaluation of lymphocyte populations in dermatomyositis shows a high percentage of B cells in the perivascular regions and an increasing frequency of T cells towards the perimysium and endomysium. T cells found within the muscle are relatively rich in CD4. In dermatomyositis, especially the juvenile-onset form, inflammation and

necrosis followed by atrophy appear in a perifascicular pattern. Perivascular lymphocytic infiltrates, typical of later disease, have not been described as an early change. Dermatomyositis may thus be the result of an immune complex deposition or a primary attack on endothelial cells. As in SLE, interferon- α/β -inducible gene and protein expression may contribute to the pathogenesis of DM. This innate immune response is characterized by plasmacytoid dendritic cell invasion.²² Consistent with the importance of immune complexes, histological abnormalities in the skin in dermatomyositis are indistinguishable from the changes in lupus.

In contrast to dermatomyositis, polymyositis and IBM do not demonstrate marked capillary changes, perivascular infiltrates are less pronounced, and T-cell infiltrates in the perimysial and endomysial regions are more pronounced. Nonnecrotic fibers may be surrounded by T lymphocytes and macrophages. The T cells are enriched for the CD8 subset. Attempts to culture these cells and look for lysis of autologous myocytes have met with limited success. There is negligible evidence of NK cell-like activity. Should cytotoxic T cells prove to be the major effector cells, it will be necessary to clone T cells to identify the antigenic targets. Most cytotoxic T cells are of the CD8 phenotype and therefore recognize their antigenic peptide in association with MHC class I molecules. Although resting normal muscle has very low class I expression, it is upregulated in regenerating and degenerating fibers found in both inflammatory and noninflammatory myopathies. Interestingly, in dermatomyositis, class I expression is upregulated predominantly in the perifascicular regions, around sites of atrophy, and near sites of cellular invasion. In contrast, in polymyositis, class I expression may be diffusely upregulated even where there is no cellular infiltrate. IBM shows a more focal class I distribution in regions of T-cell invasion. The presence of focal regions of MHC class I expression in nonnecrotic fibers at the site of activated CD8 T cells is compatible with cytotoxicity as a prime mechanism of myocyte necrosis in IBM and polymyositis. A pivotal study using transgenic mice demonstrated that abnormal accumulation of MHC class I molecules in the endoplasmic reticulum (ER) of muscle may initiate the ER stress response.²³

Proposed pathogenic mechanisms for the development of both the familial and the sporadic forms of IBM include the concept of increased transcription and accumulation of the β -amyloid precursor protein and its proteolytic fragments; abnormal accumulations of the components of lipid metabolism, including cholesterol; and oxidative stress.²⁴ These characteristics, in concert with the theory of misfolded or unfolded proteins in the context of a cellular aging milieu, appear to contribute to the pathogenesis of IBM. One of the most intriguing steps forward in the study of IBM in recent years has been the identification of mutations in the UDP-*N*-acetylglucosamine 2-epimerase/*N*-acetylmannosamine kinase gene in the recessive familial quadriceps-sparing IBM first described in Iranian Jews, but now more extensively recognized.

The role of MHC class II molecules remains to be clarified. Cultured myoblasts constitutively express high levels of class I and are negative for class II. Class II has been found to be upregulated in the endothelial cells of patients with dermatomyositis, but its expression on T cells, a marker of activation, is more prominent in polymyositis.

Finally, $\gamma\delta$ TCR T lymphocytes have been cloned from the muscle biopsy of one patient with polymyositis. Subsequent evaluation of his biopsy demonstrated $\gamma\delta$ T cells and a 65 kDa heat shock protein in the endomysial region. The relative importance of $\gamma\delta$ T cells in the spectrum of IIM is unknown.

The role of the B cells within affected muscles is not understood. It is not yet known whether they produce any autoantibodies, particularly the myositis-specific antibodies, or whether they play a role in antigen presentation for the T cells.

The pathogenic role of the autoantibodies found in patients with IIM remains uncertain. Myositis-specific antibodies (MSA) are found in 30–40% of patients, appear to delineate specific clinical entities, and each group has a strong but not absolute HLA association. In a patient with myositis and antihistidyl-tRNA synthetase (Jo-1) autoantibodies, sera available from long before the onset of symptoms or biochemical damage to muscle tissue contained the autoantibodies, suggesting that the autoantibodies were not merely a response to release of tissue antigens. The extraordinary specificity of myositis-specific antibodies for IIM and the lack of evidence for strong polyclonal stimulation in these diseases suggest that MSA are related to the fundamental causative process in IIM. Although 80–90% of patients with IIM are found to have antibodies to myosin or myoglobin, these antibodies are also found in patients with noninflammatory myopathies.

The structures bound by MSA are mostly intracellular ribonucleoproteins involved in protein synthesis, such as the aminoacyl-tRNA synthetases and the signal recognition particle (SRP). These autoantigens are found in every nucleated cell. The antibodies in general bind to conformational epitopes and, at least in the case of the antisynthetases, block enzymatic activity. It is possible that a structural property of muscle allows these particular proteins to be presented to the immune system when the cells are damaged, or, alternatively, the capacity of muscle fibers to degenerate alongside intense regeneration within the same fiber may allow these proteins to be efficiently displayed.²⁵ Recent experiments have suggested that some aminoacyl-tRNA synthetases have a direct proinflammatory role through a subsidiary chemokine-like action.²⁶

A landmark study recently determined that cultured myoblasts express high levels of autoantigens, which are strikingly downregulated as cells differentiate into myotubes *in vitro*. These data strongly associate regenerating rather than mature muscle cells as the source of continuous autoantigen supply in autoimmune myositis.²⁵

GENETICS

The IIM do not exhibit a simple mode of inheritance, and the rare familial cases mostly reflect IBM of early onset. As noted above, there are HLA associations for particular myositis-specific autoantibodies. Specifically, HLA-DR52 has a strong association (90%) with antisynthetase-positive myositis in both Caucasians and African-Americans.²⁷

KEY CONCEPTS

DIFFERENTIAL FEATURES OF MYOSITIS

- >> In dermatomyositis the earliest changes involve vessel walls, and B cells and CD4 T cells predominate in the muscle biopsy.
- >> In polymyositis and inclusion-body myositis the dominant pathologic feature is targeting and invasion of muscle cells by CD8 cytotoxic cells.

NATURAL HISTORY

The prognosis for patients with IIM varies greatly with clinical type, autoantibodies, extraskeletal muscle involvement, and the interval between diagnosis and the start of treatment.

Patients with dermatomyositis or myositis accompanying another connective tissue disease are likely to recover most of their strength with prompt and adequate therapy. Although recurrences are common, persistent profound weakness does not usually occur. Most patients with anti-Mi-2 autoantibodies also usually respond well to therapy. Strength usually recovers well in patients whose myositis is cancer related, but overall mortality due to the tumor is high. Indeed, an accompanying tumor remains one of the most frequent causes of death in patients with an IIM. The diagnostic value of serum tumor markers (CEA, CA125, CA19-9 and CA15-3) was investigated in a study that demonstrated that serial CA125 and CA19-9 assessment could be useful markers in predicting which patients will develop cancer, especially in the subset of patients without interstitial lung disease.²⁸

Patients with polymyositis fare less well, even when those with IBM are rigorously excluded. A return to normal strength is very unusual, and each recurrence is likely to be followed by greater residual weakness, even if inflammation is fully controlled. IBM has a poorer prognosis, but it is possible that the gradual decline in strength can be halted for long periods by corticosteroid and/or cytotoxic therapy if continuing inflammation is present. Severe muscle weakness and atrophy are prominent features in patients with anti-SRP autoantibodies. They have traditionally had the worst prognosis because there is rampant muscle destruction at the very outset. Those with anti-Jo-1 autoantibodies or antibodies to another synthetase are likely to respond to therapy initially, but to require continuing immunosuppression to treat frequent recurrences. In this group morbidity and mortality are heavily influenced by the progression of lung involvement. Longitudinal studies of outcomes in DM and PM patients are few. Cardiac involvement, respiratory involvement, and cancer were the main causes of death in several cohort analyses.^{28–30} Disease course is monocyclic in approximately 20% of patients, polycyclic in 20%, and chronic in the remainder.³⁰ Relapses have been noted in the initial years of therapy and after prolonged disease-free intervals; therefore, periodic surveillance is warranted for at least 2 years following remission.^{31,32}

PATIENT MANAGEMENT

The treatment of myositis is based on controlling skeletal muscle inflammation and damage. Immunosuppressive therapy is used in the initial stages of the disease to reduce inflammation and muscle damage. To date, there are very few randomized controlled trials of any of the immunosuppressive agents used; thus, therapeutic regimens and responses have remained largely anecdotal. Clinical trials to assess the efficacy of TNF- α inhibitors, tacrolimus, and rituximab are currently under way. After the initial inflammation is controlled, strengthening exercises are useful in improving functional capabilities.

CORTICOSTEROIDS

Corticosteroids are the main immunosuppressive agents used in the treatment of myositis. An initial course of pulses of methylprednisolone may be helpful, particularly in disease of acute onset, and may also be

helpful in managing disease flares. If active muscle inflammation persists or the side-effects of corticosteroids are severe, other immunosuppressive treatments are employed.

SECOND-LINE IMMUNOSUPPRESSIVE THERAPIES

The most frequently used second-line agents in the treatment of myositis are azathioprine and methotrexate. Azathioprine has been shown to reduce long-term disability.³³ Methotrexate is useful in patients with little or no response to corticosteroid therapy.^{34,35} Combination therapies, such as methotrexate with azathioprine, are useful even if patients have failed to respond to one of the agents alone.³⁶ High-dose intravenous immunoglobulin is of proven benefit in dermatomyositis.³⁷ Its usefulness in polymyositis is less predictable. Apheresis proved ineffective in a controlled blinded study.³⁸ Both cyclosporine and tacrolimus have been effective in some cases, as have cyclophosphamide and chlorambucil. The most recent therapeutic options include mycophenolate and rituximab.

MONITORING DISEASE ACTIVITY

Improvement in strength and normalization of serum CK activity are the best indirect measures of disease activity. A decrease in serum CK activity may herald clinical improvement, but corticosteroid treatment alone may reduce CK activity without associated clinical improvement. A lack of improvement in strength in a corticosteroid-treated patient may be due to the resistance of the inflammatory process, the presence of a corticosteroid-induced myopathy, and/or misdiagnosis. A diagnostic and therapeutic taper of the corticosteroids may then be warranted. If inflammation is present concurrently, other immunosuppressive agents are useful as the dosage of corticosteroids is lowered. If the CK value begins to rise, even if it is still within the normal range, and the symptoms of myositis are worsening in a patient whose disease has previously been controlled with corticosteroids, an increase in the dose may be warranted.

TREATMENT-RESISTANT MYOSITIS

Some treatment-resistant polymyositis patients have another disease. In such cases IBM or a limb girdle muscular dystrophy should be suspected. Unlike other myositis patients, those with IBM rarely, if ever, improve in strength with immunosuppressive therapy, but stabilization of strength may be achieved in some IBM patients with immunosuppressive agents.^{39,40} Patients with limb-girdle muscular dystrophies may mimic polymyositis clinically. They may have inflammation on muscle biopsy, and occasionally have associated autoantibodies. Thus, patients with a suspected IIM who do not respond to immunosuppressive therapy should undergo further evaluation, including genetic testing, to search for a limb-girdle muscular dystrophy.

NONSKELETAL MUSCLE INVOLVEMENT

Other organs frequently involved in myositis include the skin, lungs, and joints. Such organ involvement and the systemic features of myositis (fever and weight loss) usually improve with immunosuppressive therapy that controls inflammation in the skeletal muscle. Hydroxychloroquine and other antimalarials are useful in controlling the rashes associated with myositis.

DIAGNOSTIC TOOLS, EVALUATION, AND DIFFERENTIAL DIAGNOSIS

Clinical, laboratory, pathologic, and electrodiagnostic findings contribute to the proper diagnosis of IIM. Even in individuals with typical clinical features of IIM, it is essential to exclude other diseases that may have similar symptoms and signs (Table 56.5). Certain clinical features should suggest a different diagnosis. These include a family history of a similar illness; sensory, reflex, or other neurologic changes; fasciculations; a relationship of the weakness to exercise, food intake, or fasting; major muscle cramping, myotonia (difficulty relaxing a contracted muscle), or myasthenia (increasing weakness with repeated contractions); significant early muscle atrophy or hypertrophy; marked asymmetry; weakness in the distribution of the cranial nerves; and dyspnea due to diaphragmatic weakness rather than lung fibrosis.

The single most useful laboratory feature of muscle destruction is elevation of the serum CK, although this is nonspecific, and a small proportion of patients – probably < 5% – have a bona fide inflammatory muscle disease without ever having an elevated CK. Elevations of the serum levels of aldolase, serum glutamic-oxaloacetic transaminase (SGOT), serum glutamate pyruvate transaminase (SGPT), and lactate dehydrogenase (LDH) are as frequent but less specific for muscle disease. Unlike other autoimmune inflammatory diseases, inflammatory markers such as the erythrocyte sedimentation rate and C-reactive protein are often not elevated. Although some studies have shown ESR to be elevated in 50% of patients, most experts find a substantially lower proportion of IIM patients to have an elevated ESR, even with active disease.⁴¹ Likewise, hematologic abnormalities, including anemia, are uncommon and rarely related to the underlying myopathy. If a significant abnormality is found, the physician should be alert to another cause for it.

Electromyographic (EMG) abnormalities are frequently present. Although the test is useful to exclude some neurologic diseases that resemble IIM, it is painful for many patients and not useful for following the course of the illness.

Magnetic resonance imaging (MRI), especially a combination of the T₁ and the fat-suppressed T₂ (STIR) sequences, is remarkably useful in defining the extent of involvement and planning a biopsy (Fig. 56.2). Whole-body MRI was recently shown to facilitate the characterization of inflammatory myopathy, as certain patterns of muscle and subcutaneous tissue inflammation were predictive of the IIM subset (DM, PM, or IBM).⁴² Although not specific, the changes of inflammatory myopathy can provide considerable assistance in confusing cases, as well as help in choosing a site to biopsy.

A muscle biopsy should be performed in every suspected case of myositis (Fig. 56.3). Although the patchy involvement means that the biopsy may occasionally miss inflammation, confounding diagnoses, for example amyloidosis, eosinophilic myositis, dystrophy, or some metabolic myopathies as well as the important variant IBM, can only be diagnosed definitively by biopsy. The identification of autoantibodies, particularly the myositis-specific autoantibodies, has distinct clinical and prognostic use. MSAs are highly specific for myositis compared to other neuromuscular diseases, and are not simply associated with muscle inflammation.⁴³

At present, of these autoantibodies only anti-Jo-1 is commercially available, but tests for the others are carried out in research centers, and some will eventually become more widely available.

PITFALLS

It is increasingly apparent that the boundary between IIM and some genetically determined myopathies cannot be cleanly drawn. In the last several years, dystrophies with an extraordinary variety of clinical manifestations (with regard to age and distribution of weakness) have also been described.⁴⁴ Not only can inflammation be seen on

Table 56.5 Differential diagnosis of IIM

Neuromuscular disorders

- Genetic muscular dystrophies
- Metabolic myopathies
 - Disorders of carbohydrate metabolism: McArdle disease, phosphofructokinase deficiency, adult acid maltase deficiency, and others
 - Disorders of lipid metabolism: carnitine deficiency, carnitine palmitoyl transferase deficiency
 - Disorders of purine metabolism: myoadenylate deaminase deficiency
- Mitochondrial myopathies
- Spinal muscular atrophies
- Neuropathies: Guillain-Barré and other autoimmune polyneuropathies, diabetes mellitus, porphyria
- Myasthenia gravis and Eaton-Lambert syndrome
- Amyotrophic lateral sclerosis
- Myotonic dystrophy and other myotonias
- Familial periodic paralysis

Endocrine and electrolyte disorders

- Hypokalemia, hypercalcemia, hypocalcemia, hypomagnesemia
- Hypothyroidism, hyperthyroidism
- Cushing syndrome, Addison's disease

Toxic myopathies (partial list)

- Alcohol
- Chloroquine and hydroxychloroquine
- Cocaine
- Colchicine
- Corticosteroids
- D-Penicillamine
- Ipecac
- Statins and other lipid-lowering agents
- Zidovudine (AZT)

Infections

- Viral: HIV, HTLV-1, influenza
- Bacterial: staphylococcus, streptococcus, clostridia
- Parasitic: toxoplasmosis, trichinosis, schistosomiasis, cysticercosis

Miscellaneous

- Polymyalgia rheumatica
- Vasculitis
- Eosinophilia myalgia syndrome
- Paraneoplastic syndromes

biopsy in some patients, but a partial clinical response to corticosteroids can occur. Furthermore, it is increasingly recognized that mitochondrial abnormalities can be limited to groups of skeletal muscles, leading to confusion with IIM. Toxic myopathies, of course, will continue to occur with the release of new drugs, and will continue to be a possible source of diagnostic confusion.

Thus, not only must the history, physical examination, and biopsy be performed and interpreted with compulsiveness and care, but molecular diagnostic techniques must be employed by clinicians in pursuit of an

CLINICAL PEARLS

CLINICAL FEATURES THAT SUGGEST A NON-IIM DIAGNOSIS

- >> Family history of a similar illness
- >> Weakness related to exercise, eating, or fasting
- >> Sensory, reflex, or other neurologic signs
- >> Cranial nerve involvement
- >> Fasciculations
- >> Muscle cramping (severe)
- >> Myasthenia (increasing weakness with repeated contractions)
- >> Myotonia (difficulty relaxing a contracted muscle)
- >> Significant atrophy or hypertrophy early in the illness
- >> Marked asymmetry
- >> Dyspnea due to diaphragmatic weakness with normal chest X-ray

Fig. 56.2 Magnetic resonance images of the upper and lower thighs of a patient with dermatomyositis using the fat-suppressed T_2 (STIR) technique. With this technique inflammation appears as a bright signal; normal muscle is gray; and bone, fat, fascia, and normal skin are dark. Blood vessels may appear as bright spots. Note the remarkable symmetry of the inflammation. In this patient most of the involvement is in the quadriceps in the upper thighs and around the periphery of the hamstring muscle group.

Fig. 56.3 Biopsy in dermatomyositis. **(A)** Low-power (original magnification $\times 100$) view of a muscle biopsy from a patient with dermatomyositis. Note the marked variation in fiber size and the large number of atrophic myocytes, particularly at the periphery of the fascicles. **(B)** High-power (original magnification $\times 200$) view of inflammation around the vessels in the muscle biopsy of a patient with dermatomyositis. There are nearby atrophic cells and cells whose nuclei have moved away from the periphery of the cell (centralized nuclei).

accurate diagnosis and appropriate therapy. The correct response to disease that persists in the face of powerful immunosuppressive therapy is a careful re-thinking of the diagnosis, including, on occasion, re-biopsy and molecular consultation.

Spondyloarthritis

John D. Reveille

57

The term *spondyloarthritis* (SpA) (otherwise known as spondyloarthropathy) encompasses a heterogeneous group of inflammatory diseases characterized by spinal and peripheral joint oligoarthritis, inflammation of the attachments of ligaments and tendons to bones (enthesitis) and, at times, mucocutaneous, ocular, and/or cardiac manifestations. These disorders show familial aggregation and are typically associated with genes of the major histocompatibility complex (MHC), particularly human leukocyte antigen (HLA)-B27¹ (Chapter 5). The SpA include: (1) ankylosing spondylitis (AS); (2) reactive arthritis (ReA) – known previously as Reiter's syndrome; (3) psoriatic arthritis (PsA) and/or spondylitis; (4) enteropathic arthritis and/or spondylitis associated with the inflammatory bowel diseases (IBD), ulcerative colitis (UC), or Crohn's disease; and (5) undifferentiated SpA, which encompasses patients expressing elements of, but failing to fulfill, accepted criteria for one of the above diseases. In addition, isolated acute anterior uveitis (AAU)¹ and spondylitic heart disease (complete heart block and/or lone aortic regurgitation)² associated with HLA-B27 may also be classified within the spectrum of SpA.

■ CLASSIFICATION OF SPONDYLOARTHRITIS ■

There are no diagnostic criteria for any of the SpA. Classification criteria have been developed in order to provide greatest specificity in clinical studies. The European Spondyloarthropathy Study Group (ESSG) criteria for SpA were developed in 1991 and remain the basis of many clinical trials (Table 57.1).³ The modified New York criteria, developed in 1966 and modified in 1984, remain the 'gold standard' for AS.⁴ However, this depends on the presence of radiographic sacroiliitis, which takes up to 10 years to develop after the onset of inflammatory back pain. New criteria are under development for axial SpA based on the presence of inflammatory back pain that take advantage of diagnostic innovations such as magnetic resonance imaging (MRI) and HLA-B27 typing.⁵

For PsA, the classification criteria for psoriatic arthritis (CASPAR) criteria have recently been developed (Table 57.1),⁶ as a replacement for the original Moll and Wright criteria, stemming from the perception that the ESSG criteria were not 'sensitive' enough.

Preliminary criteria were proposed over 25 years ago for Reiter's syndrome (now called ReA); these criteria require the presence of 'peripheral arthritis for at least one month's duration occurring in association with urethritis and/or cervicitis.' These were modified at the Third International Workshop on Reactive Arthritis in Berlin in 1996⁷ (Table 57.1).

The International League Against Rheumatism (ILAR) juvenile idiopathic arthritis classification criteria for enthesitis-related arthritis (ERA) have been proposed for juvenile SpA (JSpA: Table 57.1). No criteria have been validated for enteropathic arthritis.

■ EPIDEMIOLOGY ■

The frequency of SpA in general and AS in particular varies in different populations and parallels the frequency of HLA-B27. The prevalence of AS varies between 0.2% and 0.7% among Caucasians,^{8–10} and has been reported in similar frequencies in eastern Asia (Table 57.2). Higher prevalences have been reported in Eskimo groups from Siberia and Alaska as well as in groups from Scandinavia, and as high as 4.3% in male Haida Indians of Canada, where the frequency of HLA-B27 is 50%.^{8–10} AS is much less frequent in Africans and Japanese, where HLA-B27 is rare.

The prevalence of ReA is unknown and probably varies over time depending on endemic rates of the sexually acquired (*Chlamydia*) and enteric (*Shigella*, *Salmonella*, *Campylobacter*) infections that trigger it. It appears that the frequency of ReA has dramatically declined in the wake of the human immunodeficiency virus (HIV) epidemic, at least in western countries, and with the adoption of safer sexual practices.

Psoriasis affects 1–3% of the general population. At least 10% of patients with psoriasis will develop an inflammatory arthritis.^{8, 10} The frequency of PsA is less clear, and is higher in those with more severe disease, though population studies among Caucasians estimate a frequency of approximately 0.1%.¹⁰

Table 57.1 Current classification criteria for spondyloarthritis**A. European Spondyloarthropathy Study Group (ESSG) criteria for spondyloarthritis**

1. Inflammatory back pain or synovitis (asymmetric, lower extremity) *plus* one of the following:
 - (a) Alternating buttock pain
 - (b) Sacroiliitis
 - (c) Heel pain (enthesitis)
 - (d) Positive family history
 - (e) Psoriasis
 - (f) Crohn's disease, ulcerative colitis
 - (g) Urethritis or cervicitis or acute diarrhea in the preceding 4 weeks

B. The modified New York criteria for ankylosing spondylitis⁴

1. Clinical criteria:
 - (a) Low-back pain and stiffness for more than 3 months which improves with exercise, but is not relieved by rest
 - (b) Limitation of motion of the lumbar spine in both the sagittal and frontal planes
 - (c) Limitation of chest expansion relative to normal values correlated for age and sex
2. Radiological criterion:

Sacroiliitis grade ≥ 2 bilaterally or grade 3–4 unilaterally

Definite ankylosing spondylitis if the radiological criterion is associated with at least one clinical criterion

C. The classification criteria for psoriatic arthritis (CASPAR) criteria for psoriatic arthritis

1. Inflammatory joint disease plus at least three points from the following features
 - (a) Current psoriasis (assigned a score of 2; all others assigned a score of 1)
 - (b) History of psoriasis
 - (c) Family history of psoriasis
 - (d) Dactylitis
 - (e) Juxta-articular new bone formation
 - (f) Rheumatoid factor seronegativity
 - (g) Nail dystrophy

D. Criteria for reactive arthritis (proposed at the International Workshop on Reactive Arthritis, 1996)

1. An acute inflammatory arthritis, inflammatory low-back pain, or enthesitis
2. Evidence of an infection preceding this condition by 4–8 weeks¹¹

E. The International League Against Rheumatism (ILAR) Juvenile Idiopathic Arthritis Classification Criteria for Enthesitis-Related Arthritis (ERA)

Arthritis and enthesitis

or

Arthritis or enthesitis with at least two of:

1. Sacroiliac joint tenderness and/or inflammatory spinal pain
2. Presence of human leukocyte antigen (HLA)-B27
3. Family history in at least one first- or second-degree relative of medically confirmed HLA-B27-associated disease
4. Anterior uveitis that is usually associated with pain, redness, or photophobia
5. Onset of arthritis in a boy after 8 years of age

Exclusions

Psoriasis confirmed by a dermatologist in at least one first- or second-degree relative

Presence of systemic arthritis

Table 57.2 The epidemiology of spondyloarthritis

Ethnic group	HLA-B27 frequency (%)	Prevalence of AS	Prevalence of PsA	Prevalence of SpA
Circumpolar groups				
Eskimos (Alaska)	40	0.4	1.5	1.5
Sami (North Norway)	24	1.8	0.23	n.a.
Asia				
China	2-9	0.11–0.26	n.a.	0.5–1.0
Taiwan	5.7	0.19–0.54	n.a.	n.a.
Vietnam	n.a.	0.05	n.a.	0.28

USA	6-8	0.2–0.5 (estimated)	0.1	0.4–1.2 (estimated)

AS, ankylosing spondylitis; HLA, human leukocyte antigen; n.a., not available; PsA, psoriatic arthritis; SpA, spondyloarthritis

The prevalence of IBD is 100–200 per 100 000 in Caucasians, with equal male-to-female ratio.^{8, 11} It is rare in people of African and Asian descent. The risk of spondylitis and peripheral arthritis varies in different reports, perhaps reflecting the subspecialty of the observer. Spondylitis occurs in as many as 15–20% of those with IBD. In general, peripheral arthritis occurs less frequently in those with UC (up to 10%) than in those with Crohn's disease (up to 20%), although its frequency tends to be higher in series where the assessor was a rheumatologist.^{8, 10, 11}

■ PATHOGENESIS ■

GENETICS OF SPONDYLOARTHRITIS

Familial aggregation

Susceptibility to AS is clearly attributable to genetic factors, with a sibling recurrence risk ratio as high as 82 and twin-based studies estimating disease heritability to exceed 90%.^{12–14} The concordance rate for AS in identical twins has been reported to be as high as 63%, compared to 23% in non-identical twins.¹² The concurrence rate for psoriasis in monozygotic twins is 70% versus 15–30% in dizygotic twins. Recurrence risk for parents and sibs of patients with Crohn's disease is 4.8% and 7%, respectively, and for UC 0.9% and 1.2%, respectively.¹³

HLA-B27 and spondyloarthritis

HLA-B27, which is encoded in the MHC class I region, confers the greatest known risk for AS, and is found in up to 95% of AS patients of European ancestry^{12–14} (Table 57.3).

Approximately 70% of patients with ReA have HLA-B27, except in Africa, where no association of HLA-B27 is seen in those with HIV-associated SpA.^{13, 14} HLA-B27 does not confer susceptibility to the initial triggering infections in ReA but does correlate with ReA severity.¹³

HLA-B27 is found in 60–70% of patients with psoriatic spondylitis and in 25% of those with peripheral PsA.^{13, 14} Up to 70% of those with IBD-associated spondylitis have HLA-B27, although no HLA-B27 association is seen with asymptomatic sacroiliitis. Approximately 50% of patients with AAU alone are HLA-B27-positive.¹

Over 35 molecular subtypes of HLA-B27 have been described this far (Table 57.4). The most common subtypes (*HLA-B*2705*, *B*2702*, *B*2704*, *B*2707*, *B*2714*) are clearly associated with SpA. Two subtypes of HLA-B27, *HLA-B*2706* and *B*2709*, found in Southeast Asia and Sardinia, respectively, appear not to be associated with AS,¹⁴ possibly due to amino acid differences in the 'B' pocket of the HLA antigen-binding cleft at positions 114 and 116 that could alter the composition and anchoring of peptides presented by these HLA-B27 subtypes. The other subtypes of HLA-B27 are too rare to have had disease associations established. One subtype, *HLA-B*2722*, was due to a sequencing error and has been withdrawn. These subtypes evolved

Table 57.3 Genetic factors implicated in spondyloarthritis

Factor	Ankylosing spondylitis (%)	Reactive arthritis (%)	Psoriasis/psoriatic arthritis/spondylitis (%)	IBD/enteropathic arthritis/spondylitis (%)
HLA-B27 frequency	90%	70%	24/60/70	7/7/70
Other MHC genes	B60 (B*4001), DRB1*0101	DR4	C*0602, B*38, B*39, DRB1*04, DRB1*07	None/DRB1*0103/none
Non-MHC genes	CYP2D6, interleukin-1 ?ANKH		Interleukin-1 KIR TNF	Nod2, IL-23R
Chromosomal regions implicated in genome scans	6p (MHC)-definite 10q, 16q-suggestive 1q, 3q, 5q, 6q, 9q, 17q and 19q-nominal		6p (PSORS1)	

HLA, human leukocyte antigen; MHC, major histocompatibility complex; TNF, tumor necrosis factor.

KEY CONCEPTS

THE GENETIC BASIS OF SPONDYLOARTHRITIS

- >> Human leukocyte antigen (HLA)-B27 comprises nearly half of the overall susceptibility to ankylosing spondylitis (AS), and contributes heavily to susceptibility to reactive arthritis, psoriatic and enteropathic spondylitis
- >> Additional influences seem to come from other major histocompatibility complex (MHC) genes, including C*0602 for psoriasis, whose identification has been confounded by linkage to HLA-B27
- >> Genetic modeling has suggested up to six additional non-MHC influences
- >> Analyses of genomewide scans implicated regions, in addition to the MHC, on chromosomes 10 and 16, and possibly on chromosomes 1, 3, 5, 17, and 19.
- >> Non-MHC genes that have been confirmed thus far include the interleukin-1 gene complex on chromosome 2q and the CYP2D6 locus on chromosome 22
- >> Genomewide association studies utilizing dense SNP mapping will likely locate many of the remaining genes in AS susceptibility

from the parent allele *HLA-B*2705* along three lines (Fig. 57.1) in three distinct geographic regions.

The exact mechanism underlying the effect of HLA-B27 on disease susceptibility has still not been determined. One theory suggests that SpA results from a unique set of antigenic peptides, either bacterial or

self, that are bound and presented by all disease-associated HLA-B27 subtypes (but not by other HLA class I molecules) to CD8 T cells, resulting in an HLA-B27-restricted cytotoxic T-cell response found only in joints and other affected tissues (the so-called *arthritogenic peptide* hypothesis). Recent data suggest that the differential association of HLA-B27 subtypes with SpA is more likely related to differentially bound peptides than to altered antigenicity of shared ligands. The strongest evidence against this theory is that a specific 'arthritogenic peptide' has yet to be demonstrated.

An alternative concept focuses on self-association as a unique property of the HLA-B27 molecule. HLA-B27 heavy chains can form homodimers *in vitro* that are dependent on disulfide binding through their cysteine-67 residues in the extracellular α_1 domain (as well as other cysteine residues in other domains) (Fig. 57.2).^{13–15} This occurs as a result of B27 misfolding within the endoplasmic reticulum. The accumulation of misfolded protein results in a proinflammatory intracellular stress response through the stimulation of interferon- β secretion. Also, HLA-B27 homodimers are detectable at the cell surface in patients with SpA, are capable of peptide binding, and are more abundantly expressed when the cell's antigen-presenting function is impaired. They are ligands for a number of natural killer (NK) and related cell surface receptors. Populations of synovial and peripheral blood monocytes, and B and T lymphocytes from patients with SpA and controls, carry receptors for HLA-B27 homodimers, including KIR3DL1 and KIR3DL2, which are receptors for NK cells, and immunoglobulin-like transcript 4 (ILT4).^{13–15} It is possible that these homodimers may act as a proinflammatory target or receptor for humoral or cell-mediated autoimmune responses. However, it is not yet known whether HLA-B27 homodimer formation is specific for, or even correlates with, the presence of SpA; in fact, most HLA-B27-positive individuals do not develop disease.

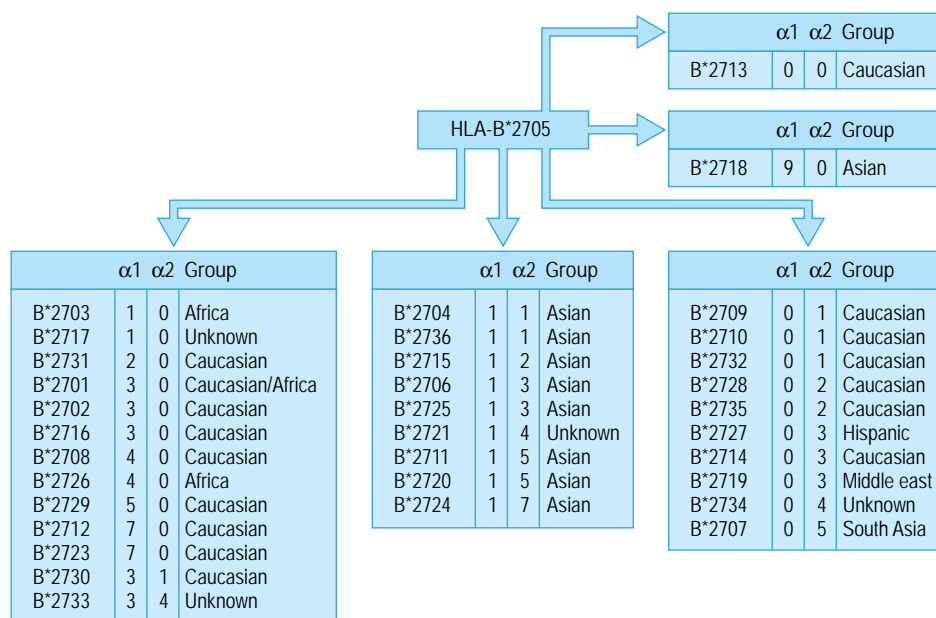

Fig. 57.1 The three major families of human leukocyte antigen (HLA)-B27 subtypes (*HLA-B*2713* and *B*2718* are assumed to have evolved separately) are denoted in relationship to the 'parent' subtype *HLA-B*2705*. Most B27 subtypes have evolved through three patterns of evolution along geographic lines. The first group, including *HLA-B*2703-B*2723* (and *B*2730*), appears to have evolved in Africa and Europe, and entails anywhere from one to seven amino acid substitutions in the first (α_1) domain, and has the second (α_2) domain identical to *B*2705*. The second group, including *HLA-B*2704-B*2724*, evolved in Asia and includes a uniform amino acid substitution in the α_1 domain and anywhere from one to seven substitutions in the α_2 domain. The third group, including *HLA-B*2709-B*2707*, evolved in southern Asia, the Middle East, and Sardinia, and has an α_1 -domain identical to *B*2705* and an α_2 domain with one to seven amino acid substitutions. Notable exceptions include *HLA-B*2713*, which has an amino acid substitution outside α_1 and α_2 , *B*2718*, which appears to have evolved separately in Asia, and *B*2730*, which shares features of the first and third groups.

OTHER MHC GENES AND SPA SUSCEPTIBILITY

HLA-B27 is not the only genetic factor involved in AS and SpA susceptibility (Table 57.3). Fewer than 5% of HLA-B27-positive individuals in the general population become affected,^{13, 14} whereas up to 20% of HLA-B27-positive relatives of AS patients will develop SpA. Family studies have suggested that HLA-B27 contributes less than 40% of the overall genetic risk for SpA¹² while the entire effect of the MHC, on the other hand, is about 50%.^{12, 16}

HLA-B60, a serologically defined HLA specificity that correlates with *HLA-B*4001* on DNA analysis, has been described as augmenting the risk for AS in both HLA-B27-positive and negative individuals from Europe and Taiwan.^{13, 14} Other HLA-B associations that have been reported include PsA-associated alleles HLA-B38 and B39,¹⁴ as well as HLA-B35 and B62 in Caucasian¹⁴ patients lacking HLA-B27.

Other MHC genes have also been implicated in AS in addition to B27, although their identification is complicated by the tight linkage disequilibrium found within the MHC, and many of the associations described thus far might be better explained by linkage to B27. These include MICA, located adjacent to HLA-B27, which encodes a marker of 'stress' in epithelial cells, and acts as a ligand for cells expressing a common activator NK receptor (NKG2D), as well as tumor necrosis factor (TNF), heat shock protein (HSP)-70, LMP-2 and LMP-7, *HLA-DRB1*01*, and *DRB1*04* alleles.^{13, 14} In addition,

*HLA-DRB1*08* has been implicated both in susceptibility to uveitis in the setting of AS and to juvenile-onset AS.^{1, 13, 14} Both *HLA-DRB1*04* and **07* alleles have been implicated in PsA, and *HLA-DRB1*0103* has been associated with enteropathic peripheral arthritis.¹³

LINKAGE STUDIES OF NON-MHC GENES

Recurrence risk modeling suggests that AS is an oligogenic disease (probable up to three to nine genes in total) with predominantly multiplicative interaction between loci.¹²⁻¹⁴ A recent meta-analysis of three genome-wide linkage studies in AS or undifferentiated SpA from the UK, North America, and France,¹⁶ including genotype data from 589 affected sibling pairs with AS, showed strongest evidence of linkage of AS to the MHC (Table 57.3), with suggestive linkage on chromosomes 10q and 16q, and areas of nominal linkage on chromosomes 1q, 3q, 5q, 6q, 9q, 17q, and 19q (Table 57.3). Although no genome-wide scans have been conducted in PsA, those in psoriasis itself have mapped a major susceptibility locus to a 60-kb interval telomeric to HLA-C in the MHC known as PSORS1, recently suggested to be HLA-Cw6,¹⁷ as well as other regions on chromosome 17q (PSORS2) and others on other chromosomes 1, 3, 4 and 19 (PSORS3-9) (Fig. 57.3). Since the first genome-wide scan for IBD was published in 1996, numerous other scans have identified seven genomic susceptibility regions, designated IBD1-9,

Fig. 57.2 After transcription of the human leukocyte antigen (HLA)-B27 heavy chain on ribosomes in macrophages, it is inserted into the endoplasmic reticulum (ER), glycosylated, and two pathways ensue. (A) The B27 heavy chain is retained through binding with calnexin and ERp57, folded into its tertiary structure and bound to β_2 -microglobulin. After that calnexin releases the complex and it is associated with calreticulum, which in turn chaperones the formation of the peptide loading on to the complex of heavy chain, β_2 -microglobulin and antigenic peptide, via the TAP proteins and tapasin. Then the trimolecular peptide complex (HLA-B27 heavy chain, β_2 -microglobulin and peptide) travels through the Golgi apparatus (A1) to the cell surface, where the antigenic peptide is presented either to the $\alpha\beta$ T-cell receptor on CD8-positive T lymphocytes or to the killer immunoglobulin (KIR) receptor on natural killer (NK) cells (A2); or (B) the HLA-B27 heavy chain misfolds in the ER, forming B27 homodimers and other misfoldings which are bound to the ER chaperone BiP. Then, they either (B1) accumulate there, causing either ER-associated degradation (ERAD) or a proinflammatory ER unfolded protein response (UPR); or (B2) the B27 homodimers migrate to the cell surface where they either become antigenic themselves or present peptide to receptors on T cells and natural killer (NK) cells.

located on chromosomes 1, 5, 6, 12, 14, 16, and 19. However, only IBD1, at chromosome 16q12, has been universally replicated (Fig. 57.3).^{12,13}

NON-MHC GENES IN SUSCEPTIBILITY TO SPONDYLOARTHRITIS

The interleukin-1 (IL-1) complex lies on chromosome 2q and includes the genes encoding the proinflammatory cytokines IL-1 α , IL-1 β , and their naturally occurring inhibitor, IL-1 receptor antagonist (IL-1RA), as well as six other homologous genes of unclear function named *IL-1F5–IL-1F10*. Although numerous studies have suggested a role for genes in this region in AS susceptibility, the actual gene(s) has yet to be identified. Recent studies from the UK, Canada, Taiwan, and the USA¹⁴ have suggested that the IL-1B association may be better explained by linkage disequilibrium with

IL-1A, which may be the primary IL-1 complex gene associated with AS. Nevertheless, it is likely that more than one IL-1 complex gene is involved in AS susceptibility, although the other associated genetic variant(s) remain to be determined. The extensive linkage disequilibrium across this region will make this identification challenging. Two studies have now also reported *IL-1A* associations with PsA.¹⁴

Approximately 5–10% of Caucasians have deficient function of the cytochrome P450 gene debrisoquine 4-hydroxylase (*CYP2D6*), an autosomal recessive trait leading to poor oxidative drug metabolism (known as the poor metabolizer, or *pm* phenotype). This gene is located at chromosome 22q13.1, and both case-control and family linkage studies support a role in AS susceptibility.^{13–15}

The *ank/ank* murine model of AS has mutations in genes influencing PPI transport, leading to low extracellular PPI levels. Different *ANKH*

Fig. 57.3 Chromosomal location of susceptibility regions indicated in genome-wide scans of ankylosing spondylitis (AS) (meta-analysis data only shown),¹⁶ psoriasis (PSORS), inflammatory bowel disease (IBD), acute anterior uveitis (AAU), spondyloarthritis (SpA), indicated to the left of the colored bar indicating the designation chromosomal region. Green, AS; red, PSORS; yellow, IBD; blue, SpA; pink, AAU.

variants have been associated with susceptibility to AS¹⁴ in men versus women with AS. However, this was not confirmed in a larger British study.^{13–15}

A number of other genes have been examined and not found to play a role in AS susceptibility, including *NOD2/CARD15*, which is a susceptibility factor for Crohn's disease, transforming growth factor- β_1 (TGF- β_1), the α/β T-cell receptor, IL-10, IL-6, *TLR4*, *CD14*, *NFKB1*, *MMP3*, *PTPN22*, α_1 -antitrypsin, androgen receptor genes, secretor status, and immunoglobulin allotypes.¹⁴ However many of these studies included only small to moderate numbers of patients, lacking adequate power to prove (or disprove) a true association for a 'small-impact' gene.

Both susceptibility to and severity of PsA have been associated with a variety of cytokine genes, including *TNF- α -308* and *TNF- β +252* polymorphisms,^{13, 14} which may explain, at least in part, the reason for the utility of TNF blockers in patients with PsA (see below), as well as IL-1A. In addition, a recent study has also implicated a role for killer immunoglobulin-like receptor (KIR) genes in patients with PsA.

GENES AND SEVERITY OF SpA

Disease severity in AS also has a hereditary component.^{13, 14} Defining severity by disease activity, and loss of function, the Oxford group demonstrated that these traits are highly heritable.^{13, 14} A region on chromosome 18 was linked to disease activity, age at symptom onset with a region of chromosome 11p, and functional impairment with a region on chromosome 2q (outside the IL-1 region). No evidence was found for an MHC contribution to severity.

INFECTION

A role for triggering infections has been better documented in SpA than in most other rheumatic diseases. The most frequent type of ReA in developed countries follows urogenital infections with *Chlamydia trachomatis* (endemic ReA).^{13, 15} Postdysenteric ReA, more commonly encountered in 'less technologically advanced countries,' follows various *Shigella* and *Salmonella* (especially *S. typhimurium* and *S. enteritidis*), *Campylobacter jejuni* and *C. fetus* and, in

Europe, *Yersinia enterocolitica* species. Microorganisms implicated in ReA share common biologic features: (1) they can invade mucosal surfaces and replicate intracellularly; and (2) they contain lipopolysaccharide in their outer membrane. Of particular note, antigens from *Salmonella*, *Yersinia*, and *Chlamydia* have been found in synovial tissues and fluids of patients with ReA,^{13, 15} often many years after the initial infection. While only bacterial fragments of the enteric pathogens have been found, evidence for viable *Chlamydia trachomatis* and perhaps *C. pneumoniae* have been demonstrated in several studies.^{13, 15} *Chlamydia* and other organisms have also been reported in the joints of healthy individuals, thus questioning the pathogenic significance of these findings.¹³ Other data, however, support the likelihood that bacterial persistence plays an important role in ReA, including the finding of specific immunoglobulin A (IgA) antibodies and synovial T-cell proliferation to the initiating infectious agent.¹³

The contribution of infection to other types of SpA is less clear. In older studies *Klebsiella pneumoniae* was implicated in the pathogenesis of AS, although recent data have not borne this out.¹³ An analysis of fecal microflora in patients with AS has instead suggested that *Bacteroides* may play a role.¹³ It may also be significant that there are high serum IgA levels in AS, although studies seeking significant IgA antibodies to a variety of organisms have been unrewarding. In fact, it has been proposed that there might be no specific infectious trigger in AS, that this may result from gut flora and may thus be 'ubiquitous.'¹²

THE GUT AND SPONDYLOARTHRITIS

In studies from Belgium and from Scandinavia, up to 50% of patients with AS have microscopic ileal inflammation seen on ileocolonoscopy.¹⁸ Moreover, two-thirds of patients with undifferentiated SpA have histologic gut inflammation. Gut inflammation in AS appears to be immunologically related to that seen in Crohn's disease. These observations have raised speculation that the inciting event in the SpA may be a breakdown of the gut-blood barrier to intestinal bacteria, though such has yet to be proven. It has been established that patients with AS and their relatives have increased intestinal permeability compared to healthy controls.¹⁷

■ PATHOLOGY OF SpA ■

One of the biggest problems with studies of the synovium in SpA and PsA is that most lesions are examined late in the course of disease, i.e., in the hips, and this only at joint replacement. Few data exist from early disease, and the difficulty with tissue access further complicates this.¹⁸⁻²⁰ Nonetheless, striking advances have occurred. For the most part the synovium in SpA resembles that of rheumatoid arthritis, with some notable differences. The synovium in SpA displays a tortuous vascular morphology compared to rheumatoid synovium, which is linear, and to have diminished lymphoid aggregates. This may be due to vascular endothelial growth factor (VEGF) and the angiogenic growth factor Ang2, whose mRNA have been observed at higher levels in the synovium in PsA compared to rheumatoid arthritis. VEGF is particularly interesting because it can synergize with RANK ligand (RANKL) to induce bone resorption and also synergize with bone morphogenetic

proteins to trigger bone formation, both processes typical of the altered bone remodeling seen in PsA and SpA.¹⁹

Increased production of CD163 in both the lining and sublining layers is seen in SpA compared to rheumatoid arthritis.¹⁸ Local production of soluble CD163 inhibits synovial T-cell activation, and levels of synovial CD163 fall with effective treatment. Increased expressions of Toll-like receptors 2 and 4 (TLR2, 4) have been shown in SpA on CD163⁺ peripheral blood mononuclear cells in patients with synovitis, which decreases with TNF- α blockade. This leads to the speculation that SpA represents an exaggerated inflammatory response of the innate immune system in genetically susceptible patients.^{18, 19}

Osteoclasts also appear to have a role, and have also been observed at the bone-pannus junction in PsA. In addition, CD14⁺ monocytes that are committed to becoming osteoclasts or osteoclast precursors are increased in the circulation of PsA patients compared to healthy controls, and decline rapidly following treatment with TNF antagonists. The clinical improvement is accompanied by a MRI-defined reduction of bone marrow edema.¹⁹

Even fewer data exist on enthesitis (the enthesium being the insertion of tendons, ligaments, joint capsules, or fascia into bone). Pathological examination of enthesitis in AS demonstrates local inflammation, fibrosis, erosion, and ossification. Immunohistochemical staining for phosphorylated smad1/5 in enthesal biopsies of patients with SpA reveals active bone morphogenetic protein signaling.²⁰

The pathology of psoriasis consists of an inflammatory cell infiltration in the dermis, with localized increased cytokine production and hyperproliferation of keratinocytes. CD4 cells are prominent in the dermis, CD8 in the epidermis; Langerhans cells are suspected to function as antigen-presenting cells. The synovium is infiltrated with CD8 T cells, is less cellular, more vascular than rheumatoid arthritis, and contains numerous B cells and macrophages.

■ CLINICAL FEATURES ■

ANKYLOSING SPONDYLITIS

Musculoskeletal symptoms

The first symptoms of AS usually appear in adolescence or early adulthood and usually start before the age of 40. The hallmark of AS is the presence of inflammatory back pain.⁵ This is a dull, persistent ache, usually described by the patient in the buttocks or hips, that is worst in the early-morning hours (between 2 and 5 a.m.), and is associated with morning stiffness lasting more than 30 minutes (and sometimes several hours to all day). The pain is classically worsened by rest or recumbency, and improves with activity. One important component of inflammatory back pain is the striking improvement that results from the use of nonsteroidal anti-inflammatory drugs (NSAIDs: usually in high doses). Although the pain may be unilateral or intermittent at first (in fact, *alternating buttock pain* is a cardinal feature of the disease),⁵ within a few months it usually becomes persistent and bilateral, and the lower lumbar area becomes stiff and painful.^{4, 5} Occasionally the first symptom of AS may come from extraspinal sources, such as AAU, peripheral arthritis, or enthesitis, especially in patients with disease onset in childhood.

Fig. 57.4 (A) Achilles tendinitis/enthesitis in a patient with reactive arthritis. (B) Schematic drawing of enthesitis, showing periosteal new bone formation, and subchondral bone inflammation and resorption.

KEY CONCEPTS

CLINICAL FEATURES OF INFLAMMATORY BACK PAIN

- >> Low-back pain that is present every day for at least 3 months
- >> Age of onset at less than 40 years
- >> Morning stiffness in the back lasting at least 30 minutes
- >> Pain that is relieved by exercise and worsened by rest
- >> Alternating-buttock pain
- >> Relief with nonsteroidal anti-inflammatory agents

The most commonly affected joints in AS patients outside the spine are in the hips and shoulders (in up to 50% of patients),²¹ with rapidly progressive destructive arthritis that necessitates joint arthroplasty at an early age. A characteristic radiographic finding is a fairly characteristic osteophytic collar that forms at the junction of the femoral head and the neck.²² Peripheral arthritis other than in the hips and shoulders is uncommonly seen in AS patients, but when present is typical of that seen in other types of SpA, with an asymmetric oligoarthritis presenting predominantly in the lower extremities.

Chest pain, often pleuritic, can be seen in patients with AS due to involvement of the costovertebral and manubriosternal joints. This and progressive thoracic spinal involvement can result in fusion of the costovertebral joints, with loss of chest expansion and a mechanical restrictive ventilatory defect.

Enthesitis (inflammation of the origin and insertion of ligaments, tendons, aponeuroses, annulus fibrosis, and joint capsules) is a classic

feature of AS and other SpA (Fig. 57.4). The most common (and most disabling) sites for enthesitis are in the foot, at the insertion of the Achilles tendon, and of the plantar fascia on to the calcaneus.²⁰

Three physical measurements have been validated and recommended by the Assessment in Ankylosing Spondylitis (ASAS) working group as useful for evaluating patients with AS specifically and with inflammatory back pain in general.¹³ The Schober test is measured as the increase with maximal forward spinal flexion with locked knees of a 10-cm segment marked on the patient's back with the inferior mark at the level of the posterior superior iliac spines. The measured distance should increase from 10 cm to at least 15 cm in an adult.¹³ Chest wall expansion with inspiration is measured with a tape measure placed circumferentially around the chest wall at the fourth intercostal space.¹³ Normal chest expansion in an adult is greater than 5 cm, although this may vary with age and gender. An occiput-to-wall distance of more than 2.5 cm is definitely abnormal. To measure the occiput-to-wall distance, the patient stands with heels and buttocks touching the wall behind and with the knees straight. The patient is asked how far back he/she can get the head, still keeping the chin in the normal position. In the straight position, the distance between the posterior convexity of the occiput and the wall is measured to the nearest 0.1 cm. The better of two attempts is recorded.¹³ Anything greater than zero is regarded as abnormal.

Another measure that is increasingly commonly employed is the measurement of lateral bending. Here the patient stands with the heels and back against the wall. There is no flexion of the knees, nor bending forward. The distance between the patient's middle fingertip and the floor is measured. The patient then bends sideways without bending the knees or lifting the heels. A second reading is taken and the difference between the two is recorded. The best of two tries is recorded for left and right. The mean of left and right gives the final result (in centimeters to the nearest 0.1 cm). Normal is greater than 10 cm.

Extra-articular manifestations

Uveitis. The anterior portion of the uvea consists of the iris and ciliary body while the posterior portion is known as the choroid. Inflammation of the anterior uveal tract is known as anterior uveitis or iritis. When the adjacent ciliary body is also inflamed, the process is known as iridocyclitis. AAU represents the typical uveitis found in SpA, occurring in about 40% of patients with AS,¹ of whom approximately 90% are HLA-B27-positive (Table 57.2).¹ Typically, AAU presents unilaterally with sudden onset, is self-limiting, and tends to be recurrent. Symptoms may include redness, pain, blurred vision, increased lacrimation, photophobia, and miosis. The diagnosis is characteristically confirmed by slit-lamp examination, which is also useful in monitoring response to treatment.

Prognosis is favorable in AAU, with resolution of symptoms within a few weeks. However, if treatment is delayed or inadequate, complications can occur; these include anterior synechiae (adherence of the iris to the cornea), posterior synechiae (adherence of the iris to the lens), which can lead to cataracts, and cystoid macular edema.¹ Rarely, increased ocular pressure is seen.¹ Macular edema has been shown to be the main factor that determines visual outcome in cases of uveitis.¹ Although AAU is the most common uveitis associated with AS, posterior uveitis has been reported and tends to be more severe, especially in those with coexistent IBD.¹

Cardiac manifestations. The characteristic cardiac abnormalities in AS are aortitis, aortic regurgitation and conduction abnormalities that are seen in up to 9% of patients with AS followed over many years. Less commonly associated cardiac conditions include pericarditis, cardiomyopathy, and mitral valve disease. HLA-B27 is an important genetic risk factor for these cardiac conditions. Aortic regurgitation is well characterized and distinguished from aortic valvular dysfunction in other disorders. Three factors contribute to the development of incompetent aortic valves: dilatation of the aortic root, fibrotic thickening and downward retraction of the bases of the cusps, and inward rolling of the edges or margins of the cusps. Aortic regurgitation is present in 2–10% of patients with AS and increases in likelihood with greater disease duration.

Cardiac conduction abnormalities, including atrioventricular and intraventricular blocks, have been regarded as the most common cardiac complication in patients with AS. Complete heart block has been found in 1–9% of patients with AS. Electrophysiologic studies show that the preferential level of block is in the atrioventricular node itself, which is in contrast with most cases of acquired complete heart block, where 80% are within or below the bundle of His. Rare complications include myocardial involvement, mitral regurgitation, and pericarditis.

Pulmonary manifestations. The incidence of pleuropulmonary involvement in AS is estimated to be 1%. The most frequently recognized manifestations are upper-lobe fibrosis, mycetoma formation, and pleural thickening. Fusion of the costovertebral joints caused by inflammation and ankylosis of the thoracic spine can lead to restrictive ventilatory impairment on pulmonary function testing. The upper-lobe fibrosis tends to be progressive. Another common finding is the presence of bilateral symmetric apical pleural thickening. Several recent studies have demonstrated that high-resolution

computed tomography is more sensitive than chest radiography in detecting the presence of pulmonary abnormalities in AS, suggesting that pulmonary involvement in AS is more common than once thought. The clinical implications of these observations remain unclear as lung involvement in AS is usually asymptomatic.

Renal manifestations. Renal involvement in AS, although uncommon, may include secondary renal amyloidosis (AA type), NSAID nephropathy, and glomerulonephritis.

Osteoporosis. Measuring bone mineral density in patients with spondylitis is complicated by false increases in spinal density from dense syndesmophyte formation, leading some to recommend quantitative computer tomography over standard dual-energy X-ray absorptiometry (DEXA) for bone mineral density measurements. Nevertheless, up to half of patients with long-standing AS have been reported as having osteopenia or osteoporosis.²³ The etiology of osteoporosis in AS is still not completely understood. Although treatment factors and decreased mobility or physical activity may lead to the development of osteoporosis in AS, histological examinations point to an osteoclast/osteoblast imbalance.²⁴

Spondylodiscitis and spinal fractures. An uncommon but well-recognized complication of AS is spondylodiscitis, a destructive discovertebral lesion also called Andersson lesion.²² Typically, these lesions are confined to the thoracic and lumbar spine, sometimes with multiple-level involvement; however, cervical spondylodiscitis has been reported. Pain and tenderness localized to the affected disk are the most common presenting features of spondylodiscitis, although it can be asymptomatic and only detected on routine radiographic examination many years later. Spondylodiscitis usually occurs at an advanced stage of AS under the form of an erosive condition related to both mechanical factors and osteoporosis. However, early spondylodiscitis can occur as a result of the inflammatory process. Patients may or may not give a history of preceding trauma.

Even trivial falls can be catastrophic for AS patients, who are at risk for spinal fractures due to their spinal rigidity and osteoporosis. The estimated prevalence of vertebral fractures in AS varies from 4% to 18%. Fractures through the disk space, the weakest point in the ankylosed spine, are most common, with the cervical spine being the most frequently affected region, followed by the thoracolumbar junction, and may, or may not, be complicated by injury to the spinal cord ranging from mild sensory loss to quadriplegia. Spontaneous atlantoaxial subluxation is also rarely seen.

Neurological manifestations. Neurological involvement in AS is most often related to spinal fracture, atlantoaxial subluxation, or cauda equina syndrome. The *cauda equina syndrome* in AS is characterized by a slow insidious progression and a high incidence of dural ectasia, although a rapid onset secondary to a traumatic event has been reported. It tends to be a late manifestation of AS, often when the disease is no longer active. The prevalence of neurologic findings in cauda equina syndrome in AS is very high, presenting with a prodrome of sensory, motor, or reflex loss before the progression to sphincter disturbance. About half of patients have pain in the rectum or lower limbs that is presumably neurogenic in origin. Case reports have also been published about the occurrence of AS with a multiple

sclerosis-like syndrome and transverse myelitis, although the association is not conclusive.

Fatigue and psychosocial manifestations. Fatigue is a common problem in patients with AS and seems to be associated with more severe disease. Sleep disturbance has also recently been reported to be as high as nearly 81% of female AS patients and 50% of male AS patients. The disturbance is closely related to pain during the night characteristic of active disease. A high level of depressive symptoms has been reported in approximately one-third of patients with AS, with women reporting more depression than men. Pain was found to be a major determinant of depression for women, but was of lesser importance for men.

AS in women. AS in women may not be as severe as it is in men, and may present with isolated neck pain in the absence of typical back pain.²⁴ There tends to be a greater delay in the diagnosis of AS in women compared to men.²⁴ Women tend to have less severe involvement of the spine, with peripheral joint involvement. A large review of the impact of AS on reproductive events on women concluded that AS did not adversely affect the ability to conceive, pregnancy outcome, or neonatal health.²⁴

REACTIVE ARTHRITIS

The classic triad of *arthritis*, *urethritis*, and *conjunctivitis*, representing what was formerly known as Reiter's syndrome, is a presenting feature of only a minority of patients with ReA (comprising only a third of the cases in some series). In ReA, the clinical features are today viewed more as a spectrum ranging from the classic triad to undifferentiated SpA. In fact, the manifestations vary among patients, depending on the genetic makeup, the triggering event, and the sequential immunologic reaction.

Typically, the features start 1–4 weeks after a triggering event, frequently identified as an enteric or urogenital infection, but often the event passes unnoticed without any specific symptoms. The syndrome starts with constitutional symptoms such as fatigue, malaise, and fever, and then is typically manifested by *asymmetric, additive lower-extremity oligoarticular inflammatory arthritis* along with an array of different extra-articular features, including a sterile oligoarticular or monoarticular and asymmetric arthritis of the lower extremities, especially the knees, ankles, and, occasionally, hips. Upper-extremity involvement is encountered less commonly. *Dactylitis* occurs in the toes or fingers, resulting in the 'sausage digits' which represent inflammation not only of the interphalangeal joints of the hands and feet, but also of the surrounding soft-tissue structures, including the tendons and subcutaneous tissue.

Sacroiliitis and *spondylitis* are less common than peripheral arthritis, although inflammatory back pain does occur. Unilateral and bilateral sacroiliac involvement and even spondylitis occur, especially in those with chronic or long-standing disease. The most common sites for enthesitis are the Achilles tendon and plantar fascia insertions, although tenderness over the symphysis pubis, iliac crest, ischial tuberosity, greater trochanters, and thoracic cage ribs can also occur.

Mucocutaneous lesion also occur that can be difficult to distinguish from PsA, especially *circinate balanitis* and *keratoderma blenorrhagica*. Circinate balanitis is an ulcerative mucosal lesion over the glans or shaft of the penis that is demarcated by a serpiginous erythematous border. The lesion is usually painless and sterile unless a superimposed

infection occurs. Keratoderma blenorrhagica is a painless desquamative psoriatic-like papulosquamous eruption and is sometimes referred to as pustulosis palmoplantaris and occurs on the palms and soles of the feet. Oral lesions have been described as shallow, painless ulcers or patches on the palate and tongue, or mucositis of the soft palate and uvula. Conjunctivitis and AAU also occur, as described in AS. Conjunctivitis may be unilateral or bilateral and is usually an early feature manifesting with irritation, erythema, and lacrimation. It is usually associated with a sterile discharge unless a superimposed infection occurs due to eye rubbing. It can be severe and occasionally progress to episcleritis, scleritis, or keratitis. Other findings seen in AS, such as cardiac involvement, do rarely occur. Although renal involvement is mainly described in the context of the urogenital triggering infectious process, sterile pyuria in conjunction with proteinuria and microscopic hematuria are sometimes encountered, although documentation of glomerulonephritis is rarely described.

JUVENILE SPONDYLOARTHRITIS

Basically there are two clinical subsets of JSpA. *Undifferentiated JSpA*, which includes peripheral arthritis and enthesitis, primarily affects the lower limbs, may also present with sacroiliac tenderness and/or inflammatory spinal pain, and also includes isolated episodes of arthritis, enthesitis, tendinitis, dactylitis, and seronegative enthesopathy and arthropathy (SEA) syndrome.²⁵ *Differentiated JSpA* (juvenile AS, PsA, IBD-related arthropathy) includes peripheral arthritis and enthesitis *plus* evidence of structural changes in JAS (radiographic sacroiliitis, spinal disease, or tarsal ankylosis) and/or specific extra-articular symptoms (e.g., psoriasis or IBD). The SEA syndrome was originally referred to the combination of enthesitis and arthritis or arthralgia as an idiopathic disease or as part of a well-defined SpA.²⁵

PSORIATIC ARTHRITIS

Skin involvement exhibits four clinical patterns. The most common type is *psoriasis vulgaris*. Nearly as common is *guttate* psoriasis. The most severe type is the *erythrodermic* variety. Finally, *pustular psoriasis* is the type most closely associated with HLA-B27. Usually the disease appears coincident with or after the onset of skin manifestations, although approximately 15–20% of patients will have pre-existent arthritis. The joint disease likewise occurs in different subtypes, as defined by the Moll and Wright classification (Fig. 57.5), including oligoarticular, asymmetric, polyarticular, symmetric, distal interphalangeal (DIP)-predominant, spondylitis (sacroiliitis), arthritis mutilans, inflammation of DIP joints (often with nail involvement (~80%)), dactylitis: 'sausage digits,' and enthesitis.²⁶ Extra-articular features include nail pitting (which correlates best with DIP involvement) and uveitis (which occurs in some series as high as 33% but in most far less). Radiographically, large eccentric erosions are encountered.

ENTEROPATHIC ARTHRITIS

The arthritis associated with IBD (enteropathic arthritis) is most commonly nondestructive and reversible. Two patterns have been recognized (Table 57.5): type 1 is oligoarticular, involving the knees and ankles more than the upper extremities. It tends to resolve in < 6 weeks. The second type has a polyarticular presentation, is more likely to involve

Fig. 57.5 Patterns of psoriatic arthritis, showing (A) rheumatoid-like distribution; (B) sausage digits; (C) distal interphalangeal involvement; and (D) psoriatic arthritis mutilans.

the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints more than the lower extremities, and is more likely to have a chronic course. The symptoms of peripheral arthritis tend to coincide with activity of the bowel disease in UC but not in Crohn's disease. Total colectomy is associated with remission of arthritis in half of patients. In contrast, axial involvement may precede the development of IBD, has no gender predilection, and resembles the development of AS. The axial symptoms do not parallel activity of bowel disease. In addition to spondylitis, an isolated sacroiliitis occurs that is often asymmetric and not associated with HLA-B27.

Mucocutaneous complications of IBD include erythema nodosum, which occurs in fewer than 10% of those with Crohn's disease and is rare in UC; pyoderma gangrenosum, seen in slightly over 1% of those with Crohn's disease and rarely occurring in those with UC; and, rarely, erythema multiforme. Painful aphthous ulcers occur in about 8% of those with UC and are rare in Crohn's disease.

The uveitis with IBD that is bilateral, posterior, insidious in onset, and/or chronic in duration contrasts with the uveitis associated with other types of SpA, which is predominantly anterior, unilateral, sudden in onset, and limited in duration. Only 46% of patients with uveitis associated with IBD are HLA-B27-positive, as opposed to 89% of the

Table 57.5 Extraintestinal manifestations of inflammatory bowel disease

Feature	Crohn's disease (%)	Ulcerative colitis (%)
Peripheral arthritis	15	10
Axial arthritis	15–20	10–15

patients with SpA. Episcleritis, scleritis, and glaucoma are more common among patients with IBD than in those with SpA.

UNDIFFERENTIATED SPONDYLOARTHRITIS

Patients are regarded as having undifferentiated SpA who do not meet criteria or clinical features of the ‘classic’ spondyloarthritis. Generally, at presentation, about 40% of patients will be classified as having undifferentiated SpA,²⁷ and the frequency of HLA-B27 reaches around 80% in Caucasians (Table 57.6). Follow-up studies suggest that over time about one-third will go in to remission and more than half will develop a ‘classical’ SpA, usually AS.²⁸

LABORATORY INVESTIGATIONS

The most useful investigations in SpA come from musculoskeletal imaging, but some laboratory tests can be informative.

Data on the correlation of erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) in the assessment of disease activity in SpA show

CLINICAL RELEVANCE

UTILITY OF HUMAN LEUKOCYTE ANTIGEN (HLA)-B27 TESTING IN THE EVALUATION OF INFLAMMATORY BACK PAIN AND SPONDYLOARTHRITIS

- >> Not indicated where the diagnosis is unquestionable, as it has little value in prognosis
- >> Although patients with spondyloarthritis of African and Middle Eastern ancestry are more likely to be human leukocyte antigen (HLA)-B27-negative, the finding of HLA-B27 in these patients has higher predictive value
- >> Most useful in patients with either inflammatory back pain without radiographic changes or with other features of spondyloarthritis (unexplained lower-extremity arthritis in a young adult, uveitis, etc.)
- >> If serologic testing is used to ascertain HLA-B27, insure the blood sample arrives in the laboratory within 24 hours of being drawn (false negatives due to cell death)

ambiguous results, although most studies suggest that CRP performs better. A recent literature review on the validity aspects of ESR and CRP in AS concluded that ESR and CRP do not comprehensively represent the disease process and thus do not have the same validity as in rheumatoid arthritis.^{13,29} Generally, it is felt that patients with peripheral joint involvement or with IBD more often have elevated ESR and CRP than those patients with axial disease.¹³ However, a normal ESR and/or CRP does not exclude the presence of clinically active AS. Synovial fluid does not differ in appearance or cytology from that of any inflammatory joint disease.

DIAGNOSIS

In most cases, SpA is largely diagnosed, or at least initially suspected, on clinical grounds. Current criteria for AS demand that the patient have radiographic sacroiliitis (at least grade II bilaterally or grade III unilaterally) in conjunction with clinical signs of inflammatory back pain and limitation of spinal mobility. However, given that up to 10 years can pass from the onset of inflammatory back pain and the development of radiographic sacroiliitis,⁵ many of those with inflammatory back pain might not have radiographic evidence of sacroiliitis.⁵ With the development of effective treatments (i.e. anti-TNF blockers), much recent emphasis has come on formulating criteria for earlier diagnosis of axial SpA, which are currently under development.⁵ These criteria take into account recent advances in MRI scanning as well as the added benefit provided in HLA-B27 testing.⁵

MEASURES OF SpA ACTIVITY AND SEVERITY

In the past few years, outcome measures have been developed and validated to quantitate disease activity, and disease severity; these are summarized in Table 57.7, including disease activity, functional impairment, metrology, and quality of life. These instruments are extensively validated and easy to administer in clinical practice, and have been shown to perform well in clinical trials.¹³

CLINICAL PEARLS

OPTIMAL UTILIZATION OF X-RAYS IN THE DIAGNOSIS AND MANAGEMENT OF SPONDYLOARTHRITIS

- >> Patient education and physiotherapy should be initiated early in the disease course
- >> Nonsteroidal anti-inflammatory drugs (NSAIDs) remain 'first-line' treatment
- >> Disease-modifying anti-inflammatory drugs (DMARDs: sulfasalazine, methotrexate) for peripheral arthritis
- >> Intra-articular/intralesional corticosteroidal injections
- >> Anti-tumor necrosis factor agents for axial disease refractory to nonsteroidal anti-inflammatory drugs (NSAIDs), peripheral arthritis refractory to DMARDs, and enthesal lesions refractory to NSAIDs
- >> Don't forget to treat coexistent/complicating conditions (inflammatory bowel disease, psoriasis, osteoporosis)

modified Stokes Ankylosing Spondylitis Scoring System (mSASSS).³⁰ As a rule, they have a low sensitivity to change (7.5% over 2 years), have been validated in long-duration disease only, and their predictive effect for disease activity is not yet ascertained.

One problem with radiographic imaging is the average decade-long interval from the onset of inflammatory back pain to the appearance of radiographic sacroiliitis.⁵ The introduction of MRI imaging of the spine and entheses has allowed not only correct anatomic description of spinal structures, but also differentiation of AS-related and unrelated inflammatory spinal lesions earlier than is possible by standard radiographs.³¹ MRI of the sacroiliac joints and spine is currently the only imaging tool to localize and quantify spinal inflammation accurately (Fig. 57.7), and is being developed as a measure of disease activity and treatment response.

Psoriatic arthritis

PsA has some rather characteristic radiographic manifestations, including asymmetric involvement, involvement of the DIP joints, and the classical 'pencil-in-cup' deformities. Also seen are periostitis, bony ankylosis, and bony erosions with new bone formation. Radiographic severity is quantitated by the modified Sharp scoring method used in rheumatoid arthritis.

The measures used in PsA to assess disease severity include the ACR response criteria, the Psoriatic Arthritis Response Criteria (PsARC), which entail improvement in at least two of the following four criteria: (1) physician; and (2) patient global assessments (on 0–5 visual analog scales); (3) tender and swollen joint scores (> 30% improvement), with improvement in at least one of these two joint scales; and (4) no worsening in any criteria. The Ritchie Articular Index is also used. The Psoriasis Area and Severity Index (PASI) is used to assess the extent of skin involvement, as well as general measures such as the target lesion score, and the static global assessment. The PASI is a composite index of skin disease severity, including an overall evaluation and quantitation of the extent of scaling, erythema, and induration weighted: (1) by severity; and (2) by body surface area. A target lesion is a single lesion > 2 cm in diameter evaluated over time by a dermatologist and that is graded for size, elevation, erythema, and scaling.

RADIOGRAPHIC IMAGING OF SPONDYLOARTHRITIS

Axial spondyloarthritis

The bottom line in the diagnosis of AS is the demonstration of radiographic sacroiliitis (Fig. 57.6).²⁷ Two outcome instruments have been introduced in the assessment of disease damage and progression in AS: the Bath Ankylosing Spondylitis Radiographic Index (BASRI) and the

Fig. 57.6 Grading of radiographic sacroiliitis, including: **(A)** grade 0–1 (normal); **(B)** grade 2–3, with sclerosis and small erosions; **(C)** advanced grade 3, with joint space narrowing and large erosions; and **(D)** grade 4 (total sacroiliac fusion).

■ DISEASE COURSE AND PROGNOSIS ■

ANKYLOSING SPONDYLITIS

Although AS is a chronic condition that can frequently have an unpredictable course, some studies suggest that those with higher levels of disease activity early in the course of the disease are more likely to have subsequent active disease in the future³⁰ (Fig. 57.8). Hip involvement has been shown to be a predictive factor for severe disease.³⁰ Other factors that may be suggestive of severe disease and severe outcome include: ESR > 30 mm/hour, unresponsiveness to NSAIDs; limitation of lumbar spine; ‘sausage’ digits; oligoarthritis; or onset at < 16 years.³⁰ Longitudinal studies in patients with AS revealed that deformities and disability occur within the first 10 years of disease.³⁰ Most of the loss of function occurred during the first 10 years, and correlated significantly with the occurrence of peripheral arthritis,

radiographic changes of AS in the spine, and the development of ‘bamboo’ spine.³⁰

Significant risk factors for work disability from several studies include older age, longer disease duration, lower level of education, reduced physical functioning, pain, and more physically demanding jobs.²⁹ Patients with AS have an overall frequency of disability and economic costs similar to that of rheumatoid arthritis.^{13, 27} However, the impact of newer agents, such as anti-TNF drugs, on the natural history of this disease remains to be seen.

REACTIVE ARTHRITIS

Early studies of outcome in ReA suggested a relatively poor prognosis. More recent studies, however, have found that, in general, the prognosis of ReA appears to be fairly good.³² Most cases appear to remit within 6 months of onset. Given the introduction of highly effective biologic agents such as anti-TNF blockers, it is likely that the long-term prognosis in ReA will improve even further.

Fig. 57.7 (A) Magnetic resonance imaging of the sacroiliac joints, showing areas of marrow edema (indicated by arrows) on STIR sequences. (B) Lateral spine, showing enhancement of the insertion of the annulus fibrosus on the disk (arrowheads) and subchondral bone (arrows). (C) Involvement of the subchondral bone of the apophyseal joints.

Fig. 57.8 The ‘classical’ course of ankylosing spondylitis, showing disease progression from shortly after disease onset in 1947 until just before the patient’s death in 1973. The slight improvement between 1972 and 1973 was due to his having gotten total hip arthroplasties.

PSORIATIC ARTHRITIS

Recent studies – although before the introduction of biologic treatments – have shown that the prognosis of PsA is worse than previously suggested.^{17, 19, 26} In one large cohort, 40–57% of patients had deforming arthritis, 17% had³ five deformed joints, and up to 19% of patients had disability. Overall, more rapidly progressive disease was associated with a greater number of actively inflamed joints, the early use of disease-modifying agents, and the presence of HLA-B27 and B39. Patients with PsA have also been shown to have increased mortality, which is associated with a high ESR, high ‘advanced’ medication usage, and early radiographic damage.

JUVENILE SPONDYLOARTHRITIS

Although not extensively studied, the prognosis in JSpA is guarded.²⁵ Available data suggest that children with disease activity for more than 5 years are more likely to be disabled. In fact, the probability of remission was only 17% after 5 years of disease. Nearly 60% of children with JSpA have moderate to severe limitation after 10 years of disease. What is not clear is the extent to which the outcome in juvenile-onset AS is different from that in adult-onset disease.

TREATMENT (TABLE 57.8)

PATIENT EDUCATION AND PHYSIOTHERAPY

A great deal of educational information is available for patients (www.spondylitis.org and www.arthritis.org). Unsupervised recreational exercise improves pain and stiffness, and back exercise improves pain and function in patients with AS and other types of SpA, but these effects differ with disease duration. Health status is improved when patients perform recreational exercise at least 30 minutes per day and back exercises at least 5 days per week.¹³

THERAPEUTIC PRINCIPLES

TREATMENT PRINCIPLES FOR MEDICAL MANAGEMENT OF SPONDYLOARTHRITIS

- >> Patient education and physiotherapy should be initiated early in the disease course
- >> Nonsteroidal anti-inflammatory drugs (NSAIDs) remain ‘first-line’ treatment
- >> Disease-modifying anti-inflammatory drugs (DMARDs: sulfasalazine, methotrexate) for peripheral arthritis
- >> Intra-articular/intralesional corticosteroidal injections
- >> Anti-tumor necrosis factor agents for axial disease refractory to nonsteroidal anti-inflammatory drugs (NSAIDs), peripheral arthritis refractory to DMARDs, and enthesal lesions refractory to NSAIDs
- >> Don’t forget to treat coexistent/complicating conditions (inflammatory bowel disease, psoriasis, osteoporosis)

MEDICAL TREATMENT

Nonsteroidal anti-inflammatory drugs

NSAIDs remain the starting point of treatment, and many patients will attain satisfactory symptom control with these agents alone. There are no strong data to suggest the superiority of any specific NSAID in patients with SpA. NSAIDs when taken regularly (not on an as-needed basis) and at full anti-inflammatory doses seem to slow down the radiographic progression of AS.³² Cyclooxygenase-2 antagonists are recommended

mainly for patients with proven peptic ulcer disease. Of concern is the association of the use of NSAIDs with flares of colitis, suggesting they should be used with care in this setting.

Disease-modifying anti-inflammatory drugs (DMARDs)

Sulfasalazine. The efficacy of sulfasalazine in the treatment of peripheral joint involvement in AS and other SpA has been shown in many controlled trials, including two large multicenter studies in the USA and France.³³ Its efficacy in axial disease is unproven; in fact, it has not been shown to be effective in most studies. Coincident with improvement in peripheral arthritis is a fall in acute-phase reactants such as the ESR and CRP.

Other DMARDs. Although less well studied than sulfasalazine, methotrexate has been shown to be effective in the treatment of peripheral arthritis and psoriasis in patients with AS and other SpA. Its efficacy in treating axial arthritis has not been established.

The use of leflunomide in patients with SpA has not been well examined. Limited data suggest it is useful in the treatment of peripheral joint involvement in SpA as well as PsA, although not for axial involvement.

Corticosteroids. Although not well studied in patients with AS, many clinicians add low-dose glucocorticoids to the management of active SpA where NSAIDs or DMARDs fail to achieve a satisfactory response. On occasion pulse steroids have also been utilized. Given the lack of controlled data as to their effectiveness, the side effects of long-term glucocorticoid therapy (including osteoporosis, a major cause of morbidity in AS patients, and possible worsening of psoriasis) and the emergence of more effective treatments, their use is not recommended unless more effective treatments are not available.

Intra-articular/intralesional corticosteroids

Intra-articular and peritendinous injections of depot steroid preparations are frequently employed by clinicians for symptomatic relief of local flares, although they have not been extensively studied in controlled trials. Injecting around the Achilles tendon is generally not recommended because of the risk of tendon rupture.

Antibiotics

Early data suggested that a 3-month course of antibiotics in the acute phase after disease onset may have a beneficial effect on the course of ReA, specifically in those with *Chlamydia trachomatis*-triggered ReA, but not in other patients.³⁴ Recent long-term follow up data, however, suggest that tetracycline treatment did not change the natural history of the disease.³⁴ In another recent study, however, a 3-month course of ciprofloxacin in the acute phase was found to have a beneficial effect on the long-term prognosis.³⁴ It is clear that early antibiotic therapy for chlamydial genital infections can prevent ReA, although the same is not true for enteric pathogens. For patients at risk for enteric infections and ReA, prophylactic antibiotics should be considered. There is no evidence that antibiotics have any place in the management of other SpA.

TNF- α blockers

Infliximab. The use of a chimeric monoclonal antibody to TNF- α (infliximab) at 5 mg/kg of infliximab every 6 weeks has been shown to be beneficial in both the axial and peripheral manifestations of AS in both open-label³⁵ and in placebo-controlled clinical trials.³⁶ The onset of action is quite rapid, usually following the first infusion, with over 80% of patients achieving > 20% improvement in measures of disease activity. Improvement was seen not only clinically but also radiographically, with clearing of lesions suggestive of disease activity on MRI.

Etanercept. The soluble TNF- α receptor, etanercept, given 25 mg subcutaneously twice weekly, has been shown to be effective in the treatment of AS in patients in a 4-month randomized double-blind placebo-controlled study of 40 AS patients.³⁷ Improvement was sustained in an open-label extension of this study for over 10 months. Similar positive results were seen in another longitudinal study of 10 SpA patients studied in the UK, with statistically significant improvement seen not only in all clinical and functional parameters, but also in MRI-detectable enthesal lesions, of which 86% either regressed completely or improved.³⁸ Similar positive results have been reported in PsA,³⁵ where substantial improvement was seen in both the joint and enthesal involvement as well as in the extent and severity of the psoriatic skin lesions. The Food and Drug Administration has approved the use of etanercept in the treatment of both AS and PsA.

The use of TNF blockers in the treatment of AAU is less clear, however. Recent data suggest they are useful, at least those comprised of monoclonal antibodies.¹

Adalimumab. Adalimumab has been approved by the Food and Drug Administration for the treatment of AS and psoriatic arthritis, used at a dose of 40 mg every other week.³⁸ In patients in whom biweekly dosing does not suffice, weekly administration may be necessary.

ASAS guidelines for the use of TNF blockers. Because of the high cost and potential side-effect profiles of TNF blockers, as well as the finding that many patients with AS are well controlled with NSAIDs or sulfasalazine alone, the ASAS working group formulated and subsequently revised guidelines for the use of TNF blockers. These take into account both the patient's and physician's assessments of disease activity (Table 57.9).³⁹

SURGICAL TREATMENT OF AS COMPLICATIONS

Because the hip is the joint most commonly involved in patients with AS, total hip arthroplasty is the most common surgical procedure.²¹ Heterotopic new bone formation can be a potential problem.

Limited prevalence data suggest that patients with AS, even those with mild disease, are at increased risk for vertebral fracture, often resulting in neurologic compromise.²⁴ In general, halo vest immobilization is recommended. Surgical intervention may be necessary when neurological impairment is seen. The fixed kyphotic deformities seen in patients with advanced AS are of considerable distress to patients and can result in substantial functional impairment. A small minority of AS

Table 57.9 International Assessment in Ankylosing Spondylitis (ASAS) consensus statement for the use of antitumor necrosis factor (TNF) agents in patients with ankylosing spondylitis (AS)

1. For the initiation of anti-TNF- α therapy:
 - (a) a diagnosis of definitive AS
 - (b) presence of active disease for at least 4 weeks as defined by both a sustained Bath AS Disease Activity Index (BASDAI) of at least 4 *and* an expert opinion based on clinical features, acute-phase reactants, and imaging modalities
 - (c) presence of refractory disease defined by failure of at least two nonsteroidal anti-inflammatory drugs during a single 3-month period, failure of intra-articular steroids if indicated, and failure of sulfasalazine in patients with peripheral arthritis
 - (d) application and implementation of the usual precautions and contraindications for biological therapy
2. For the monitoring of anti-TNF- α therapy: both the BASDAI and the ASAS core set for clinical practice should be followed regularly
